NICOLAS, GATÉ, and DUPASQUIER (*C. R. Soc. Biologie*, December 3rd, 1921) have treated certain chronic skin lesions, such as prurigo, polymorphic dermatitis, erythrodermia, and papulo-vesicular eczema. The technique employed was the injection of blood by venous puncture, followed by the reinjection of the blood into the muscles of the buttock. From three to ten injections were made at intervals. Of the eight patients whose histories are recorded, four appear to have been completely cured, while the other four were benefited to a varying degree. The interest of the observations lies in the peculiar nature of the reactions which occurred after the injections. Apart from the usual sequelae, such as leucopenia, fall of the blood pressure, and diminution in the blood platelets, there were encountered a number of clinical conditions, such as acute pain in the lumbar region passing off in ten minutes, a marked evening rise of temperature, severe arthralgia, and even a non-suppurative arthritis. That these are definitely to be ascribed to the serotherapy there appears to be little doubt in the authors' minds.

THE CHOROID PLEXUS AND PSAMMOMAS.

AN EMERITUS LECTURE DELIVERED AT THE MIDDLESEX
HOSPITAL, FEBRUARY 7TH, 1922.

BY

SIR JOHN BLAND-SUTTON, F.R.C.S.,
CONSULTING SURGEON TO THE HOSPITAL.

THE ruffle-like structures, called choroid plexuses, which float in the ventricular fluid of man's brain, have aroused the curiosity of anatomists for centuries, yet they took little more interest in them than gardeners take in weeds. Of late these plexuses have acquired importance for pathologists and clinicians.

THE CHOROID PLEXUS.

In the living brain a choroid plexus is red, for it is well supplied with blood, and the fringes floating in pools of

FIG. 1.—Diagram of a mammalian brain showing the distribution of the choroid plexuses.

cerebro-spinal fluid resemble the beautiful long red gills of the larva of the Alpine salamander.

In order to understand the relations of the various plexuses it is worth while to review their distribution. The velum interpositum with which they are so intimately connected, indeed it is the supporting structure of the plexuses, is a fold of pia mater, and arachnoid, buried in the brain when the primary cerebral vesicles turn backward to envelop the primary encephalic vesicles which ultimately become the hind and fourth ventricles; the middle vesicle persists as the aqueduct of Sylvius. All parts of the velum which come in close relations with the ventricles are richly fringed with vascular epithelial tufts. These tufts reach their highest development along the fringes of the velum, which extend into the lateral ventricles, and its cornua. The fourth ventricle has a rich choroid plexus, and the villi are big in the lateral recesses; the orifices of these infundibula the plexus floats in the fluid of the pool called the cisterna magna. There is a mystery surrounding the lateral recesses of the fourth ventricle. The orifice of each recess is in close relation with a slight depression in the floor marking the centre of the circle formed by the anterior semicircular canal; a spot marks the osseous remnant of the bulbous endolymphatic; the communication may be direct, or through the intervention of a chain of ossicles to which classical and picturesque names have been applied—tripus, scaphium, and claustrum. This is the remnant of an old communication between the internal system of the internal ear and the intracerebral circulation of fluid?

In the fourth ventricle of the horse's brain the choroid forms a conspicuous ring around the orifice of each lateral recess. When the brain is removed from the skull the plexus forms a bunch and conceals the opening, but if the brain is immersed in water the orifice of the recess is easily seen.

The plexus at each lateral recess rests upon the roots of origin of the glosso-pharyngeal and vagal nerves.

The orifices of the lateral recesses of the fourth ventricle establish communication between the ventricular cavities of the brain and the general subarachnoid spaces of the brain and spinal cord. The foramen of Magendie, described as existing at the apex of the calamus scriptorius, is, I believe, an artefact. It does not exist in the horse.

Choroid plexuses are highly developed arachnoid tufts and often contain cholesterol. They are glandular organs and secrete cerebro-spinal fluid. The plexus differs from other secreting glands in having its secreting cells on its outer surface. There is convincing experimental proof that most of the cerebro-spinal fluid is secreted above the aqueduct of Sylvius.

My interest in the clinical importance of the choroid plexuses was aroused especially in relation with the plexus of the fourth ventricle. In 1836 J. H. Dooty, at that time medical officer at the asylum, Powick, sent me the cerebellum and bulb, obtained from a lad aged 17, who died there after manifesting violent symptoms indicating a tumour of the brain. On examining the parts I found the fourth ventricle crammed with a tangled overgrown choroid plexus, forming a mass as big as a bantam's egg. The lateral recesses were tightly stuffed with villous tufts. The interventricular communications were completely obstructed and the aqueduct of Sylvius much dilated.

The boy died from an overgrowth of the choroid plexus of the fourth ventricle. In the terms of pathology it was a crowd of papillomas. This is by no means an isolated case, and I have collected several similar examples, and each had a tragic ending. Papillomatous masses in the fourth ventricle illustrate the baneful effects environment imposes even on simple tumours. Parallel conditions occur in the larva, in the conduits of the urinary organs, and in the bladder. In the brain the danger lies not only in the interruption of the interventricular waterway, but also from the pressure the clumps at the orifices of the lateral recesses exert on the roots of the vagi. It also teaches that complete stoppage of the interventricular communications may be as inimical to life as complete obstruction of both ureters.

FIG. 3.—Microscopic characters of a choroid plexus (Morowaka).

FIG. 2.—Lateral view of the cerebellum and medulla of a horse showing a cluster of the choroid plexus around the orifice of the lateral recess of the fourth ventricle.

PSAMMOMAS.

In 1867 Virchow coined the term "psammoma" (sand tumour) for a tumour peculiar to the meninges of the brain and spinal cord. Pathologists subsequently confirmed this observation, and the energy of surgeons has made them familiar objects in museums. Such tumours resemble in shape and size walnuts, and are occasionally bilateral. They are frequent in relation with the lateral recesses of the fourth ventricle, and set up serious symptoms by pressing on the medulla and the roots of the vagus and other important cranial nerves. As a rule, they have slender connexions with the brain. In a remarkable case described by Strahan in 1883, a soldier had bilateral recess tumours. Savage examined the specimen and reported that the tumours had no attachment to the cerebellum, or pons, or medulla, and were loosely connected with the membranes about them.

The microscopic structure of psammomas supports the idea that they arise from choroid plexuses and arachnoid tufts. The tissue is arranged in whorls, and in the centre of each vortex there is a blood vessel. The idea of a cluster of villi

surrounded by fibrous tissue, and the whole encapsuled by a laminated capsule, is irresistible. When the mass of choroid plexus, or arachnoid tuft, is completely invested and growth arrested, the sequestered epithelium becomes impregnated with cholesterol sand. Hence the picturesque names—psammoma, cholesteatoma, and pearl tumour; some gleam like mother-of-pearl.

The infiltration of these tumours with cholesterol resembles the deposition of lime salts in dead uterine fibroids.

A psammoma infiltrated with cholesterol is a dead tumour, but it rarely dies before it has wrecked the life of the man or woman by damaging brain or spinal cord.

The clinical symptoms produced by these extraordinary tumours sometimes permit of exact localization; often they are complicated tangles, difficult to unravel even with the help, separately or combined, of a neurologist, otologist, ophthalmologist, radiologist, and a physician. In this lecture I am mainly concerned with pathologists.

VILLI IN GENERAL.

Villi of various kinds play a large part in our lives, mainly for good, sometimes for evil. Soon after conception the chorion of the embryo becomes shaggy with exquisite villi, and although the villi are extremely delicate structures they are able to erode the maternal structures with which, in the normal course of events, they come in contact, embed themselves and develop a placenta.

It occasionally happens that they fail to form a placenta, change into peculiar grape-like bodies and transform into what is commonly known as a "hydatid mole." Some years ago obstetricians were startled by the discovery that such erratic changes in the villi sometimes lead to disastrous consequences in fertile women, for these altered villi behave like malignant tumours. They erode blood vessels, colonize the blood, disseminate and quickly cause death. This particular change is now known as chorionic cancer.

There is another variety of villus which occurs only under pathological conditions. Occasionally the ovary is occupied

by a cyst, usually unilocular, and its walls are covered by crops of papillomas closely resembling, in structure and appearance, the grape-like bodies of hydatid moles. The papillomas are able to erode the cyst wall and project on its outer surface.

There are two varieties of ovarian papillomatous cysts. One is clinically innocent. The other exhibits malignant properties, for it is not only erosive but it recurs locally and disseminates. I have published an account of one which set up secondary deposits in the mediastinum, and the papillomatous buds eroded the sternum and appeared as papillomatous cysts under the skin. When the papillomas erode the walls of the cyst the minute collections of shed epithelium become

engrafted on the peritoneum, and warts, sometimes in thousands, arise from them. When examined microscopically such implanted warts are often found to be encapsuled by peritoneal exudation, and thus recall in miniature the encapsuled psammomas of the meninges.

CONCLUSION.

The study of these conditions, I venture to think, helps us to understand the nature of the psammoma. This tumour begins in an overgrown clump of choroid plexus, or arachnoid tufts. The epithelium capping the clumps is bathed in cerebro-spinal fluid, and becomes enclosed in a capsule of plastic exudate which stratifies and organizes. It is known that peritoneal exudation will encapsule sterile foreign bodies, ovarian papillomas, calcified epiploic appendices, intestinal and subserous uterine fibroids, and even a coagulated collection of sterile fluid or blood clot.

The villi of the arachnoid erode bone, as the Pacchionian foramina prove; chorionic villi, normal and abnormal, can penetrate the walls of

the uterine, and ovarian papillomas in a favouring environment erode bone.

Surely this is sufficient evidence to justify the removal of psammomas from the miscellaneous group at present labelled endotheliomas.

THE TREATMENT OF GASTRIC ULCER.*

BY

SIR WILLIAM HALE-WHITE, K.B.E., M.D.,
CONSULTING PHYSICIAN TO GUY'S HOSPITAL.

THE treatment of gastric ulcer labours under two great preliminary difficulties. The first is that it is often diagnosed as present when it is not. That this bears on treatment is shown by the very many gastro-enterostomies that have been performed for a supposed ulcer when none has existed; sometimes the gastro-enterostomy has had to be undone later.

Among the conditions the symptoms of which have often been erroneously ascribed to gastric ulcer is disease of the teeth and gums; cure of this may lead to the disappearance of symptoms thought to be due to a gastric ulcer. In the middle of the last century it was believed that young women suffered from haematemesis due to vicarious menstruation, and in one large textbook this was stated less than thirty years ago. When this belief was discarded, young women with dyspepsia and haematemesis were said to have a gastric ulcer, but gradually doubt was thrown on this view. Then, although these young women rarely died of their disease, a

few deaths occurred, and no ulcer was discovered. Some surgeons opened the stomach for this bleeding and observed that the blood did not proceed from an ulcer but from a general oozing over a considerable area. To this condition the name "gastrostaxis"† has been given. It is commonest in young females, is occasionally seen in young men, and rarely kills. The opinion has been expressed that this condition is one of minute multiple ulcers, but there is evidence of its being a distinct clinical entity. Many cases of gastrostaxis are diagnosed as ulcer, and, as they almost always recover, the treatment of gastric ulcer may be thought to be more successful than it is.

There is no doubt that disease of the appendix, of the gall bladder, and even a stone in the kidney, may cause symptoms that are set down erroneously to gastric ulcer. Duodenal ulcer, carcinoma of the stomach, and various functional dyspepsias may be mistaken for it. All these conditions lead to errors of diagnosis sufficiently often to make most opinions expressed as to the results of treatment of no value. Other diseases are occasionally confounded with gastric ulcer, but not frequently enough to invalidate our views as to treatment.

When we consider the individual symptoms of gastric ulcer we also find ourselves in difficulties. Haematemesis may be completely absent, even when the ulcer is large, and is frequently seen in other diseases. The same is true of occult

* Being the introductory paper to a debate on the treatment of gastric ulcer at the Royal Society of Medicine, February 2nd, 1922.

blood. Some sufferers from ulcer never have pain, many only complain of it at long intervals. It is common enough in various other conditions. Vomiting is an inconstant symptom; indeed very frequent sickness is strongly against the presence of an ulcer. Neither deep nor superficial tenderness are reliable symptoms, and it is generally allowed that an examination of the gastric contents may be of no help. My object is not to imply that the diagnosis of gastric ulcer is impossible—indeed, a skilful clinician can often infer its presence pretty confidently—but to show that the conditions which may be mistaken for it are so numerous and common, and that its own symptoms are so variable, that most statistics as to the success or failure of medical treatment are quite untrustworthy.

Examination by the x rays will often reveal an ulcer itself, it will also show the spasm of the gastric muscle (incisura) opposite to it. By this means we may obtain also further indications of the presence of an ulcer, such as hour-glass spasm, diffuse spastic distortion and delay in emptying from pyloric spasm, organic hour-glass stomach from cicatrization of an ulcer, and increased peristalsis from organic pyloric stenosis. Many radiologists supply us with beautiful pictures that are invaluable, but those produced by some are of little use. It may be that an ulcer although present is not demonstrated by the x rays, but that does not alter the fact that the only way in which we can be so sure of the existence of an ulcer that the case should be used in statistics employed to estimate the efficiency of medical treatment, is to see the ulcer with the x rays. It must be actually seen, for although the various manifestations of spasm are often highly suggestive of its presence, yet each of them may be evident when no ulcer exists. What is sorely needed is a series of cases showing on an x-ray plate an ulcer, and examined again with the x rays six months later to see if the ulcer is healed.

Our second difficulty is concerned with causation. We know how to treat a few diseases—for example, malaria and syphilis—before the cause was discovered, but generally treatment is imperfect until the cause is apparent. Clinical observations and experimental work indicate that a gastric ulcer is due to the local effect on the stomach of bacteria or toxins produced in another part of the body, and that when the gastric patch damaged by them has been formed the excavation of the ulcer is promoted and its healing retarded by the acidity of the gastric juice. It is probable that the incriminating factor is not always the same and that there are different varieties of ulcer due to different causes. Whether ulcers in human beings are formed by endogenous gastrotoxins is not known, but judging by Bolton's experiments it is possible. Still we do not yet know the cause of a gastric ulcer with anything like the certainty with which we are able to say that a diphtherial ulcer is caused by the diphtheria bacillus or a syphilitic ulcer by the *Spirochaeta pallida*. Putting aside traumatic ulcers and those due to irritant poisons, only twice have I been able to say, even after death, that I really knew the cause of an ulcer: once there were definite tubercles on its peritoneal covering and I saw the beautiful specimen exhibited here by Dr. McNee showing syphilitic spirochaetes in the wall of an ulcer. Nevertheless there is sufficient evidence for the view above mentioned for it to be strongly advisable, in every case of gastric ulcer, to remove any distant possible source of infection, be it in the teeth, appendix, or gall bladder, disease of any of these being commonly associated with gastric ulcer. More rarely such a source may be elsewhere—for example, tonsils or nose.

We are much encouraged in the treatment of ulcers of the stomach by the undoubted fact that they show a natural tendency to spontaneous cure. Those inadvertently caused by operations get well, those produced by experiments on animals heal under appropriate conditions, many seen in the post-mortem room show signs of healing, indeed they may be found quite healed; the fact that an ulcer by its cicatrization causes an hour-glass stomach or pyloric stenosis indicates that the attempt at cure has been made.

Perforation from an ulcer is much more common in women than in men; post-mortem evidence shows us that in women ulcers are more frequently multiple than in men. Therefore, it appears that we know of two distinct varieties, one multiple in many cases, a frequent cause of perforation and found chiefly in women, usually between the ages of 20 and 30; the other usually presenting itself clinically as a chronic ulcer, not so often seen to perforate nor so frequently multiple, and found chiefly in men between the ages of 30 and 40. It is very likely that there are subdivisions of each variety

depending upon the infective agent. The first is usually spoken of as an acute ulcer, the second as a chronic. This terminology is unfortunate and confusing; the words "acute" and "chronic" merely refer to time. It is believed that some in the group named chronic may begin as acute, but if there are two distinct groups with different characteristics, should the disease be of the first variety it cannot be changed to the second because it has lasted a long while.

Fabor of Copenhagen² also describes two distinct diseases under the term ulcer of the stomach. The first, corresponding to acute ulcer, is ulcer of the corpus or "woman's ulcer"; it is commonest in young women, is usually situated on or near the lesser curvature; apart from perforation the symptoms are not severe and in many cases unrecognized, the ulcer getting well spontaneously. The second, corresponding to chronic, he calls juxtapyloric ulcer; it is commonest in men, its symptoms are frequently severe and often need surgical interference. But these names, although better than acute and chronic, are far from perfect, for the first variety is not confined to women nor the second to men, nor is the ulcer invariable in its situation in either. It would tend to clear thinking to abolish all these names, which are attempts at sharp and descriptive distinctions which do not exist, and to call the first commonly spoken of as acute ulcer A, and the second, ulcer B.

The first usually does not reveal itself on x-ray examination, and generally gives only slight symptoms; indeed, there may be none until perforation or s.

Therefore it is often very and especially so because, as we have already seen, the diagnosis of gastric ulcer has many pitfalls. Consequently it is impossible to gather accurate statistics as to the result of treatment. All we can say is that there are a number of patients, especially young women, who would a few years ago have been said to be suffering from a gastric ulcer, but some of whom we now believe owe their symptoms to other conditions already mentioned at the beginning of these remarks; others may have what is called an acute ulcer, a woman's ulcer, or ulcer A.

What shall we do with them? First search for a source of infection and, if possible, remove it; this may lead to the disappearance of the symptoms. If it does not, the outlook is still good, for the natural tendency of this class of ulcer is to heal completely. Put the patient to bed; rest in itself is good, and our diet will not contain enough calories for much work. The food must not be such—for example, meat or meat extractives—as will lead to the secretion of much acid; it must not be mechanically or chemically irritating; it must be capable of passing quickly and easily through the stomach; it must not stimulate this organ to excessive contraction, and must be sufficiently nutritious. I am accustomed to employ milk and raw egg, beaten up in it, in the proportion of two eggs to each pint of milk, giving 7½ fluid ounces of this every two hours during the sixteen hours the patient is awake, and an extra feed if she happens to wake in the night. It is almost always unnecessary to peptonize the milk, but this may be done if the patient does not mind the taste. This gives 1,600 calories a day. Unless she has a distaste for it, she should take some olive oil; she is much more likely to be able to do this if the very best quality is given, that, namely, which comes from the first expression; if necessary, it may be flavoured with a little black coffee; the patient may have it as often as she cares for it in the day, provided it is not nauseating. Its advantages are that it is a food, bland and unirritating. It restrains the secretion of acid and it is a mild aperient. One fluid ounce contains 560 calories. The total daily caloric value of our diet is now about 1,700 calories, which is enough for a patient lying in bed; she does not lose weight on it. Ulcers cannot be expected to heal if the body is under-nourished. Any dietary which leads to considerable loss of weight is wrong. In former days, when rectal feeding was common for gastric ulcer, many patients failed to get well because they were starved severely; it is impossible to prevent this on rectal feeding.

The chief drug should be an alkali to counteract the gastric acidity; sodium bicarbonate is frequently chosen with excellent results, but if it leads to distension lime water or magnesium may be substituted. Not less than 25 grains of bicarbonate three times a day should be given. Tincture of belladonna checks the secretion of acid and excess of gastric movement. A good mixture is sodium bicarbonate gr. 25, tincture of belladonna m 10, bismuth subcarbonate gr. 15, tragacanth powder q.s., with chloroform water to make

one fluid ounce; this may be given thrice daily. If an aperient is required, magnesia is the best. This treatment can generally be easily borne for six weeks; it is very simple. I have used it for many years, and patients do well on it. Several authors change the diet as the case progresses. There is no need for this; we cannot see how the cure is proceeding, and we are more likely to cure and prevent relapses in proportion as we are thorough in treatment. Many diets published are complicated; the simpler they are, the more likely are directions to be obeyed.

Cases are much too often treated in a half-hearted manner. If the doctor decides that the patient ought to be treated as though she had a gastric ulcer, let her be so treated, and not just sent away with a bottle of medicine. We have no means of estimating, in the class we are now considering, how much the stomach was ulcerated when the patient was first seen, nor how the cure is progressing, therefore I would suggest certainly not less than four weeks on the treatment—I always try to get six. Perhaps some of the mildest cases are thus treated too long, but it is better to do this than to treat some for too short a time, so that they fail to get well or relapse. The time spent in bed must vary with the case: four weeks may be desirable, but often it is well, earlier than this, to get the patient up in a chair for part of the day, out of doors if possible, provided she is warm. A little massage to the limbs helps to keep her in good condition. When the period on this diet has come to an end she may by degrees return to normal food, but this should always be plain, without much meat, and she should always masticate thoroughly. Unless perforation takes place these patients do not require the aid of a surgeon.

Although, thanks to x-rays, chronic ulcer, or ulcer B, is much more easy of diagnosis, the treatment is more difficult and uncertain. We badly want, as I have already said, a series of cases with x-ray pictures before and after medical treatment. Should it be decided to try this we employ the same as that just given, but it will have to be more prolonged; it must last for many weeks.

This class of ulcer is more common in hospital than in private practice. Hospital patients cannot afford to be away from work long; surgery is easier in hospital than in private practice, a cure from surgery is quicker and probably more certain than that from medical treatment, and nowadays the risk to life from surgical treatment is slight; therefore surgical treatment, whilst often desirable anyhow, is especially so for hospital patients. Medical treatment should only be undertaken for those in whom the x-rays do not indicate an ulcer—for they certainly fail to reveal it sometimes—or show that it is small. Its progress should be watched by x-ray examinations, say every six weeks; if it is not getting less the surgeon should be consulted, as he should if relapse has occurred after medical treatment, or this fails to benefit the symptoms.

In trying to decide when to adopt surgical treatment we must remember that even if the ulcer heals, pyloric stenosis, hour-glass stomach, or perigastric adhesions may follow, and all require surgery. Perforation, subphrenic abscess, fatal haemorrhage, or transition from a simple to a carcinomatous ulcer may occur at any time before complete healing, and when this has taken place dyspepsia may remain.

We shall hear from surgeons the best way of dealing with these ulcers. Gastro-enterostomy is by no means a universal panacea; it often fails to do any good. On the other hand, in suitable cases—for example, pyloric obstruction—the benefit is so great that if the patient is one for whom this operation is indicated it had better be done at once without waiting for medical treatment.

Perforation requires instant surgery. Every hour's delay greatly increases the risk of death. However severe the haemorrhage in the class of acute ulcer or ulcer A, no attempt should be made to stop it by surgery. Experience has shown that this increases very considerably the risk of death, for patients blanched by bleeding bear operations badly, and further, as the bleeding is often from many points, the surgeon cannot stop it; it can almost always be controlled by nature, aided by medical help. If in the second class haemorrhage is severe, operation should not be undertaken until the patient has recovered from its effects; then the question should be discussed whether it would be wiser for the surgeon to interfere with a view of preventing a second bleeding; certainly after the second he should operate to prevent a third. Even the rare event of death during a profuse haemorrhage should not make the physician blame himself for failing to ask surgical aid; had the patient been operated upon during the bleeding the chances of recovery would have been lessened.

The medical treatment for bleeding from a gastric ulcer of any sort is absolute rest in bed in a quiet room without visitors and enough morphine subcutaneously to keep the sufferer gently under its influence. If the symptoms show that the bleeding has been excessive, 2 grains of calcium chloride dissolved in water should be injected intramuscularly night and morning; this dose definitely increases the coagulability of the blood. No food or drink should be given by the mouth or otherwise for twenty-four hours. At the end of this time, dextrose in solution in tap water, 525 grains to the pint, may be given by the rectum, half a pint two or three times a day. But it is unlikely that all this can be retained and absorbed, so that the patient hardly gets more than 800 calories a day this way. Although this is by far the best rectal feed it is a starvation diet on which it is improbable that ulcers will heal; therefore, in two or three days at latest some milk in hourly or half-hourly feeds should be given by the mouth, and, as rapidly as possible, the patient should be got upon the diet already mentioned as suitable for ulcer of the stomach. I strongly suspect that, in the past, very many cases have been lost from too prolonged rectal feeding and consequent starvation; it must be remembered that these patients are often already under-nourished from severe dyspepsia at the time the bleeding occurs. Transfusion may be of great help, but, in the nature of things, it is unfortunately often impossible to carry it out at short notice.

Drugs given by the mouth are of very little value in arresting gastric bleeding; sometimes it has appeared that a drachm of liquor ferri perchloridi, with an equal amount of glycerin to facilitate swallowing, has stopped the haemorrhage, but as it is so nasty and may cause vomiting I have given up ordering it. During recovery iron is useful, but it should not be given as an acid preparation, nor in a form likely to cause indigestion. Reduced iron, the old-fashioned dialysed iron, or the saccharated carbonate may be prescribed. Lerico water in doses of two fluid ounces suits some and the minute quantity of arsenic in it may be helpful.

The treatment of other results of gastric ulcer, such as organic hour-glass stomach, pyloric obstruction, subphrenic abscess, and perigastric adhesions, is entirely surgical. Of these, the treatment of the last is likely to be disappointing, for, although in some cases surgery is brilliantly successful, in others either the adhesions are such that the surgeon cannot give much relief or the patient, usually a woman, has become from long painful suffering such an introspective invalid that her symptoms continue after operation, and she wanders from operation to operation, each of which she welcomes. We should, before opening the abdomen of a woman for chronic disease, remember that a certain number drift into this very unsatisfactory class. I remember one in whom operation led to complete relief of her pain due to adhesions so long as she was in the hospital; when she returned to sympathetic friends the pain came back; we readmitted her to hospital and it soon disappeared. It is not a bad aphorism to say that we should think twice as long before opening the abdomen of a woman for chronic disease as we should before opening that of a man.

Opinions differ widely as to the frequency of syphilitic gastric ulcer; in this country it is regarded as very rare. If in a case of gastric ulcer there is evidence of syphilis, anti-syphilitic treatment should be given, but surgery may be required for some of the results of the ulcer, such as hour-glass contraction. Whether the treatment by intramuscular injection of calcium salts combined with giving parathyroid by the mouth, as suggested by Vines, will prove of benefit time will show. Here also it will be well to watch the progress by occasional x-ray examination of the ulcer.

To sum up. Statistics as to the result of medical treatment are at present valueless. Unless it perforates, the acute ulcer or ulcer A requires only medical treatment. Very many of the other class will derive most benefit from surgery; but ulcers should not be operated on when bleeding.

GASTRIC SYPHILIS.*

BY

DAVID J. GALLOWAY, M.D., F.R.C.P. (EDIN.).

LECTURER ON THE PRACTICE OF MEDICINE, KING EDWARD VII SCHOOL OF MEDICINE, SINGAPORE.

GASTRIC SYPHILIS was described twenty-five years ago by Lancereaux in his *Traité de Syphilis*, and references to it in Continental medical periodicals and textbooks are not infrequent. In medical literature in the English language mention of such a condition has been rare, one very excellent textbook dismissing it in exactly seven words. Recently, however, reports of cases are becoming more frequent, especially from America, and we are driven to one of two conclusions—either that this manifestation of syphilis is becoming more common, or that we are awaking to the fact of the existence of such a pathological entity. My belief is that, while by no means common, it is not the excessive rarity it is commonly assumed to be. There may be reasons for this belief: first, there is the ethnic one, my experience having been wholly among Asiatics; in them syphilis, especially untreated syphilis, is not only more common, but presents other pathological pictures than in Europeans; and, secondly, because my introduction to the disease was of such a nature as to leave in my mind no trace of doubt as to its existence, and to induce an attitude of mind favourable to its discovery when present.

My first case occurred thirty years ago, when I was asked by the medical attendant of a patient to see him in consultation; a diagnosis of pyloric cancer had been made.

CASE I.

The patient was a Straits-born Chinaman, 45 years of age, in easy circumstances. I had frequently met him, and recollected him as a well-built man inclined to stoniness although of active habits. When I saw him I had difficulty in recognizing him. He was emaciated to a degree, with dry wrinkled skin of that lemon tint which we associate with cachexia in Chinese. His features were sharpened, and he had the "facies" of serious illness. His complaint was all of his stomach. About five months previously he entirely lost his appetite, and had vague uneasiness in the region of the stomach. If he forced himself to eat his discomfort was often so great that he had to excite vomiting to obtain relief. Soon the vomiting became spontaneous; lately he had vomited only once or twice in the twenty-four hours, bringing up a large quantity. He

Examined the abdomen, he noticed a considerable bulging of the waves of peristalsis were visible through the parchment-like abdominal walls, but in what direction these were travelling I have no note. By palpation and percussion a much dilated stomach was mapped out, the greater curvature being well below the umbilicus when in the horizontal position and sinking into the pelvis when he sat up. An attempt to elicit a "splash" was too much for the patient, and he was sick, bringing up a large quantity of greyish sour-smelling liquid. After he had rallied a little it was possible to make a much better examination, and a firm mass was felt lying mostly under though somewhat to the outer edge of the right rectus, about the level of the umbilicus. This mass had a considerable degree of movement. The liver and spleen were both palpable. I concurred in the diagnosis already made.

With a view to lessening his discomfort, the stomach was washed out and half a grain of calomel was given every hour for six hours, the idea being to lessen fermentation. He was allowed clear soups only, with sips of hot water, and the calomel was to be continued in doses of one-sixth of a grain every two hours. Ten days later I was asked to see him again, as such changes had taken place as to require a revision of our diagnosis. Since the washing out and passage with calomel the vomiting had stopped; he seemed to digest what was given him, his appetite was coming back, and there was difficulty in keeping him on the diet prescribed. All this may occur in a case of pyloric cancer, as the result of local treatment at first, but the surprising factor in this case was that the tumour disappeared as rapidly as appearing.

On my second visit I found the patient in much altered mood. Although still very emaciated, he looked much better, had lost the "facies," there was no bulging in the abdomen, it was, in fact, aphoid, and it was easy to feel a well-defined thickening, slightly higher and a little more to the right than the position previously occupied by the tumour. The liver and spleen were still enlarged; there was some mercurial stomatitis, but not excessive. To put briefly, the antisyphilitic treatment was continued, the diet gradually increased, and in a little over four months he had gained his lost weight and was in robust health. He lived for twenty-five years after that, a life saved by a mere accident, and a striking reminder of our limitations. There was no history of syphilis obtainable.

The patient I now show is peculiar in that he is the only European in my series. He came into my hands eighteen months ago, his case having been diagnosed by one medical

man as cancer of the stomach, and by another as cancer of the head of the pancreas.

CASE II.

He is not very robust now, but at the time of which I speak he was little more than a skeleton. A peaked swelling stood up in the centre of an area bounded above by the ensiform cartilage, below by the umbilicus, and laterally by the costal margins—an inch below the centre of the epigastrium. His hollow abdomen tended to exaggerate the prominence of the swelling, but viewed horizontally it stood higher than the level of the sternum. It moved with deep inspiration, could be freely palpated without pain, and it lacked the stony hardness which we associate with malignancy. He had been living on soups and milk for months. There was no dilatation of the stomach, no jaundice, and no spinal symptoms, but there was enlargement of both the liver and spleen, which his emaciated state rendered easily palpable. He had a history of syphilis, acquired in South Africa twelve years before and practically untreated, and stigmata of the disease were many. He was given 1 gr. doses of the yellow iodide of mercury three times daily until signs of saturation appeared, and then an intravenous injection of 0.6 gram novarsenobenzol. I left for Australia soon after, enjoining him to have a thorough treatment, but that is all he has had. The improvement worked by even such limited dosage is very great.

There are other than tumour manifestations caused by syphilis, and the case I have chosen to represent a second class is that of a Japanese woman from Taipeng.

CASE III.

Her history was that three months before she lost her appetite, but could still digest soft foods. That ability was early lost and she began to vomit. Gradually a new which was nearly constant, not much very much so by vomiting. From medical advice, her diet had been restricted to milk, and even that had latterly been returned. In the vomited matter she had lately noticed small clots of blood, and, if the effort had been severe, bright red blood was brought up towards the end of vomiting.

Signs of syphilis were many, and the only objective local sign was a thickening in the epigastrium, a little to the left of the middle line, very tender on manipulation, and there was enlargement of the liver. She was not pregnant. She was much exhausted, and there was a strong acetone smell in the breath. The treatment had been very careful, and much resource had been shown in it.

For twenty-four hours she had nothing but full doses of sodium bicarbonate in hot water, most of which she retained, and then an intravenous injection of "914." The vomiting ceased at once, and after her dread of vomiting had gone she began to take food in quantity. After a course of combined mercury and "914" she returned home cured.

As typical of a third, and by far the most numerous, class of case I have taken that of a Chinese merchant, 53 years of age, a man much above the average both physically and mentally.

CASE IV.

He had contracted syphilis twenty-two years previously, for which he had had no treatment. I had seen him frequently, his usual complaint being a sore mouth, caused by mucous patches, irritated by excessive cigar smoking. A few weeks on iodine and mercury perchloride and the application to the patches of a chromic acid paint cleared this up, and he stopped treatment as soon as comfort was attained. On this occasion, however, it was not the tongue, all his complaint was of his stomach. For over a month he had been losing all desire for food and had trouble in digesting what little he took. His troubles were worst at night so that he had been taking no food after 2 p.m., but even then he had sometimes to induce vomiting before he could sleep, and the vomit was the food he had taken early in the day, little changed.

Examination of the abdomen was not satisfactory as he was rather stout with a thick abdominal wall, but enlargement of both liver and spleen could be made out. Deep pressure in the epigastrium elicited only slight tenderness. The tongue was remarkably clean though still showing thin mucous patches, and the mouth was, generally, in good condition. The urine was free from albumin and sugar, but there was a pronounced indican reaction. He was treated for dyspepsia and both medicines and diet frequently changed because of the entire lack of success with any.

After three weeks of this he was decidedly worse, had lost much weight, and had developed a slight temperature. Anorexia was absolute, but his thirst was great. A trace of sugar was found in the urine and malarial parasites were found in the blood, probably accounting for the temperature. A better examination of the abdomen could now be made, but the skin had assumed the dry, inelastic feel and lemon tint of cachexia. It was while making this examination that it flashed into my mind that I was dealing with a case of syphilis of the stomach, and acting on this, I discarded all other treatment and gave an intravenous injection of novarsenobenzol. The result was almost theatrical, and in a day or two he was able to eat with relish. A course of treatment soon restored him to his normal condition, minus the sore tongue.

You will probably agree with the statement that in its power of mimesis of other diseases syphilis runs hysteresia a close second, for however much my description of the cases

* Read before the Malaya Branch, British Medical Association.

may have fallen short, I can assure you that clinically they were very presentable pictures of three distinct gastric conditions—malignant tumour, gastric ulcer, and a subacute gastritis. I was fortunate in getting histories of infection in the majority of my cases—I say fortunate, as you all know the difficulty of obtaining a medical history of any kind from a native, to whom the acquisition of a venereal disease is a mere incident. From the histories and from a consideration of all the collateral circumstances in those from whom no history could be obtained, I was led to the conclusion that all of them were the result of the acquired disease. The youngest, and also the earliest after the date of infection, was a female, 28 years of age, with a clear history of infection six years previously.

The comparative rarity of the definite tumour formation may be judged when I say that in thirty-five years I have encountered it only seven times; all were males, and only one European. In three the symptoms of obstruction with dilatation of the stomach were very definite; in one, the European, there were signs of a partial obstruction, and in the remaining three there were no signs of obstruction whatever. In the European the swelling lay in the middle line, and yet it produced some obstruction as only fluids could pass. This can be explained only on the hypothesis that, by its size, it caused a distortion of the gastric planes and thus obstruction. In the other non-dilated cases the site of the tumour was to the right of the middle line, so that, of the seven cases, six were in the pyloric region.

I am unable to add anything to our knowledge of the pathology of these conditions as I have had no fatal case, but writers on this subject are fairly well agreed as to the changes to be found. These are two—syphilitic endarteritis and gummata formations. Of the latter three forms are discrete gummata scattered all over the mucous membrane, flat diffuse gummata, and gummatus tumour. I do not think there is much room for doubt that these tumour cases were of the latter variety. Although I have had no death I believe myself justified in stating that the course of these cases would differ little from that of the most acute type of malignant disease. In none, excepting the European, did the history of gastric trouble extend beyond six months. The condition of the dilated cases was grave enough to warrant a belief that they were within measurable distance of their end, and, what with the absolute anorexia, the abeyance of gastric function and the cachexia, I do not think that the course of the non-dilated cases would have been much longer than the dilated. The European dated the beginning of his symptoms back twelve months. Early diagnosis is therefore a desideratum, and to that end it would be a prudent measure, having diagnosed an organic lesion of the stomach, either to confirm or eliminate syphilis by a Wassermann or Noguchi test.

The only symptom which might give a pointer is the nature of the pain. While there do occur cases of malignant disease of the stomach which throughout their course are "silent," they are the exception. Pain in malignant disease is usually a prominent symptom, occurring erratically, radiating widely, always severe, often indeed agonizing, disappearing completely for a time. Pain in gastric syphilis is never at any time pronounced, but it is always there, dull and constant, sometimes better, sometimes worse, especially at night, and limited to a zone extending right round the body a little below the level of the diaphragm. There is of course always the possibility of such cases merging into malignancy, as old syphilitic lesions do in other parts of the body, and it would not surprise me if the case shown to-night should, in its half-treated condition, follow that course.

The second group of cases, those mimetic of gastric ulcer, are not as a rule difficult of diagnosis. Though vomiting is a symptom, the excessive vomiting in the illustrative case is unusual, and unless of spinal origin not easily explained. The symptoms common to all were thickening, sometimes almost amounting to tumour formation, in the epigastrium, tenderness on palpation, vomiting, and the presence of blood in the vomited matter. Taking the three cardinal symptoms of gastric ulcer, pain, vomiting, and hæmorrhage, and discussing them seriatim, it is possible to go some distance towards establishing a diagnosis. Pain in gastric ulcer is brought on, or much aggravated by, eating, and is relieved to a corresponding extent by vomiting. It is usually located in one spot, a "point of pain," is intense, and there is generally a point of referred pain, usually in the back. In ulcerated gummata of the stomach, which I take to be the pathological condition, there is a constant substratum of pain, not much

aggravated by eating, but greatly so by the effort of vomiting, radiating laterally, and forming a girdle of pain which, as usual, is worse at night. Vomiting is common to both conditions.

Hæmorrhage in gastric ulcer is usually copious, coffee-ground, or bright red, according to its time of retention. In gummatus ulcer the blood comes up only with food, is in small clots, and bright red only at the end of a severe effort of vomiting. There is a possibility of a true peptic ulcer developing in a stomach which is the site of syphilitic endarteritis.

The third class—those resembling subacute gastric catarrh—are more common than is generally supposed. They are Asiatics, and they range from those with few symptoms to those in whom the local condition verges on tumour formation.

Some assistance in diagnosis may be had from test meals, as all the cases in which it was given had a pronounced hypochlorhydria. They are too few to generalize upon, but it is significant that the condition was the same in all.

To summarize briefly, there are two symptoms and three signs. The symptoms are, first, anorexia—I know of no condition in which it is so absolute, excepting in some early cases of malignant disease—and second, the nature of the pain. The signs are, first, enlargement of the liver (and occasionally also of the spleen), with smooth outline, present in three-fourths of all cases; secondly, rapid development of cachexia; and thirdly, stigmata of syphilis.

The real test is the empiric, the therapeutic, and that may be applied both from its negative and positive aspects. It seems to be immaterial what care is expended or with what ingenuity drugs and diets are tried and changed, the result is nil. On the other hand, when specific treatment is begun, the change is immediate, often dramatic. In the pre-salvarsan days, from which period the most of my cases are taken, the prescription of choice was calomel $\frac{1}{4}$ grain, with sodium bicarbonate 10 grains, and heavy magnesium carbonate 10 grains, given thrice daily with hot water on an empty stomach, and continued until signs of mercurial saturation appeared. After the first day or two, as soon as mercury began to be absorbed, improvement began and was generally very rapid. There was always the possibility that local action shared in bringing about the improvement, but now that is eliminated and negatived, as intravenous injection of novarsenobenzol acts on the stomach condition immediately.

SOME PRINCIPLES OF AFTER-TREATMENT IN ACUTE ABDOMINAL DISEASE.*

BY

H. W. L. MOLESWORTH, F.R.C.S. ENG.,

FOLKESTONE; LATE SURGICAL REGISTRAR, LONDON HOSPITAL.

This paper is founded on the results of trying the more modern methods of after-treatment in a series of just under 300 cases of acute abdominal disorders, on which I have operated in the last two years. During the same period I had the opportunity of observing many cases operated on by others, and, since they were seen, it is impossible to avoid taking them into consideration.

An attempt has been made to follow the results of post-mortem examinations and the appearances observed at second operations, and to bring these findings to bear on technique and on after-treatment.

In surgery some older methods are being abandoned for those we believe to be better; but in nearly all conditions it is being increasingly recognized that the operation is but a part of the treatment. It is also becoming manifest that, apart from the particular manipulation called the operation, the great therapeutic agent is rest. It is astounding to realize how little we have advanced in basic principles of treatment since the time of Hilton. With all our elaboration of technique, the almost universal objective of surgery is to provide the patient with an easier task in overcoming the damaging agent.

At the conclusion of an emergency laparotomy the patient is left with a double task. He has to repair the ravages of his disease, and to overcome those portions of the damaging agent which the surgeon has left behind. He has also to repair the injuries inflicted by the surgeon, who, unlike the

* Paper read before the Kent Branch, British Medical Association, at Bromley, December 8th, 1921.

cells and fluids of the body, cannot accomplish his task without inflicting damage.

The dual repair involves many processes—excretion of toxic substances, manufacture of antibodies, multiplication and migration of cells, besides the patient's essential metabolism. Practically the only way in which we can hope to influence any of these processes is by securing for the patient physiological rest. The medical attendant, therefore, when all goes well, holds a purely watching brief. He must be prepared to act solely as a trained observer. He must be familiar with the living pathology of acute abdominal disorders, and must have a constant mental picture of what is going on in "this abdomen at this time." He must be able to diagnose at the earliest possible moment any variation from the normal convalescence. His is the responsible—and often thankless—task of deciding when a surgeon is to be called in again. He has the difficult task of doing nothing amidst the sometimes silent opposition of nurses and relatives. The treatment after operation for an acute abdominal condition is, therefore, rest; but there are certain indications for a departure from this waiting attitude.

Shock and Toxaemia.

Without discussing the genesis of shock in detail, it may safely be said that it is produced by one or more of the following factors, and that, little as we knew about it seven years ago, further knowledge makes its explanation more difficult:

1. Trauma and exposure, especially of abdominal viscera.
2. Mental and emotional impressions; pain or unfelt painful stimuli.
3. Loss of fluid from the body by haemorrhage, vomiting, or diarrhoea.
4. Loss of heat.
5. The absorption of certain poisonous substances, toxins—bacterial and non-bacterial—for example, histamine.

Its salient features are mental torpor, "pinched" facies, cold extremities, usually, but not invariably, a rapid pulse rate, and quite late a falling blood pressure. Shock is usually most severe some hours after the damage is accomplished. A slow pulse is not unusual in a patient otherwise in a state of shock. It is usual to find a patient whose peptic ulcer has perforated with a slow, full pulse, 60 to 70, yet he is cold, clammy, and evidently suffering from severe shock. One would feel more confidence in making the diagnosis from the feel and appearance than from a consideration of the chart. Patients whose blood pressure falls steadily during an operation seem to have but small chance of surviving.

Treatment.

In the absence of exact knowledge of its pathology we are compelled to treat symptoms. Thanks to Crile, we know how we may prevent severe shock. These methods are based on the elimination of noxious stimuli, maintenance of body heat, and replacement of lost fluid. These, too, are our sheet anchors after shock has been produced. What the patient requires is: *Rest*, mental, physical, and physiological. We can give him this with an adequate dose of morphine. Do not let us withhold this drug, and if it is to be of any use it must be given in full dose. Let the patient's rest and the state of his pupils be the guide to dosage. *Warmth*. The best way is by means of the electric hot-air bath; where this is not available, hot blankets and bottles. The supply of heat should be continued up to but not quite as far as the sweating point. *Fluid*. This serves three purposes: (1) It maintains the volume of the blood; (2) it can supply heat; (3) it diminishes thirst and provides a vehicle for the excretion of toxins. We can give whole blood if a suitable donor is available; it must be given intravenously, and the citrate method or that by means of Kimpton's tube are the most convenient methods. We may give gum solutions (Bayliss), which should be given intravenously. The effect of these is more sustained than the next. We can give various isotonic solutions, of which 5% think glucose (1 oz. to a pint) is the most satisfactory. Intravenous, subcutaneous, rectal and oral methods are available. If the patient can take fluid by the mouth—and here lies the great virtue of gas and oxygen anaesthesia—it seems infinitely more pleasant and just as satisfactory to give fluid in that way.

The Question of Stimulation.

Drugs such as strychnine, digitalin, ergot, adrenaline, and pituitary extract may all have a pressor effect on the vasomotor system. All available evidence goes to show that this

effect is transitory, and is succeeded by a fall to a lower blood pressure than existed before the administration. It is therefore inadvisable to use them in the treatment of shock.

Posture.

Raising the foot of the bed and bandaging the extremities should aid the circulation of blood in the vital centres. Practically the position may do good in severe shock and can do no harm. It is, however, very rare for a patient to need more than rest as supplied by morphine, and warmth as supplied by hot bottles.

Toxaemia.

In the absence of exact knowledge of the chemistry of the circulating toxins we know of no drug or combination of drugs which can deal with the complex chemical poisons we know toxins to be. It is the patient who must elaborate the drugs which are required. We think that it is the spleen, the liver, and the endocrine system which are concerned with antitoxin formation; but we cannot give any orders to these viscera. What we can do is purely passive. We can supply rest. We can, by reducing protein intake, reduce the exogenous urea formation—again giving rest. We can reduce the work thrown on the excretory organs. We can supply a vehicle for excretion. The indications are therefore to abolish protein intake, to allow rest and sleep, and to give fluid.

General Management of the Case.

All the indications we have so far examined demand rest. Rest and sleep are essentials, and for their attainment comfort is necessary. In many cases we cannot secure comfort without giving morphine, and the indications and contraindications for its use must be discussed. Morphine adds a burden to the excretory organs and lowers their efficiency, it masks symptoms and signs which should be apparent, it makes for diminished intestinal movement, and is said to increase intestinal distension. On the other hand, morphine is very often the only drug which will secure rest and sleep, and the patient who does not rest will very likely die.

The first objection is real and must be faced. It is a disadvantage which I believe is outweighed by its advantages. It is a disadvantage that might be equally urged against the use of anaesthetics. The second objection is also true, and offers the sole contraindication. We must not give morphine while trying to decide for or against a second operation, but the decision should be made quickly. The third objection contains a truth and also a fallacy; morphine diminishes intestinal movements, but I hope to show that this is desirable. It is in cases which present complications, such as obstruction, adhesions, peritonitis, and the like, that the repeated administration of morphine is called for. These conditions will produce distension without morphine. In a straightforward case morphine is not required after the first twenty-four hours. In the first hours a night's sleep works a startling change. Morphine is, nevertheless, indicated if the patient be restless and in pain after twenty-four hours so long as we are confident that further operation is not indicated.

The next thing that makes for comfort is the unrestricted intake of fluid by the mouth. Quantity need never be restricted, but it is wise to let each drink be small until we are sure that vomiting is not being induced by it.

The avoidance of all unnecessary interference with the patient makes for comfort. Enemas, feeding, and injections are particularly disturbing if repeated. Sometimes patients are almost treated to death. As soon as possible let the patient be nursed in the position of greatest comfort. There should be as few dressings as possible, tubes should be removed early, and syringing and all fiddling with the wound avoided. After an operation for appendicitis patients do best in Fowler's position, and on the right side, but they can safely be got out of this somewhat uncomfortable position after forty-eight hours. Good nursing as regards washing, oral cleanliness, and arrangement of bedding and bed rests, adds enormously to comfort. When there is vomiting after the first twenty-four hours the stomach tube is the best way of stopping it; it is uncomfortable, and, if the patient will not co-operate, painful; but once a patient has experienced the extraordinary relief of having an empty stomach he will desire its repetition. It is quite frequently a life-saving measure.

Dressings.

A clean case wants dressing when the stitches come out or when for any reason it is desirable to inspect the abdomen.

A suppurating case wants dressing only as often as pus soaks through to the outside of the dressing. Fomentations should be avoided as far as possible. They are apt not to be sterile, and are indicated only where there is a spreading cellulitis of the abdominal wall which we desire to localize as an abscess which can be drained.

Drainage.

In this connexion facts oppose much that is traditional. It is possible to drain the whole peritoneum for but a short time—about twenty-four hours. Experimental work and numerous necropsies show that any foreign body, such as a drainage tube, is isolated by plastic lymph adhesions within a very few hours. This statement is true for a dying individual; it is likely to be even more true for one who is going to survive his infection.

The foreign body, having been shut off by the above-mentioned layer of lymph, continues to drain the sinus it has produced for itself, and to drain this sinus only (Fig. 1). The discharge soon ceases once the offending tube is removed. Sometimes in removing the tube a portion of the barrier is torn; a gush of pus is the result (Fig. 1). The drainage tube is therefore useless after the first twenty-four hours (approximately). It is also dangerous; I refer only to that portion which projects into the peritoneum: the barrier of lymph is invaded by coils which convert it into granulation tissue. The granulation tissue becomes young fibrous tissue; eventually it contracts and becomes mature fibrous tissue. I have thus traced the genealogy of a fibrous band of adhesions. The longer the tube is left, the more complete is the evolution towards fibrous tissue and the denser the resulting band. In peritonitis the evolution towards true fibrous tissue (permanent) seems to have three common sites where it progresses to completion. These are: the vicinity of drainage tubes, of a residual abscess, or of traumatism or blood clot—for example, scar of uterine stump. I will quote three illustrative cases.

CASE I: Perforated Duodenal Ulcer.—S. K., male, 31. Operation twelve hours after perforation. Peritoneum flooded with bile-stained glairy fluid. Perforation closed, and a posterior no-loop gastro-enterostomy was done. Drainage tube through a stab wound above the pubes. The operation took thirty-five minutes, and he left the theatre in good condition. The tube was left in five days. Ten days after operation he developed obstruction. At his second laparotomy the peritoneum was clear of adhesions except in the track of the drainage tube. Here there was a dense, well defined band adherent to and obstructing the small gut. This was divided, and the wound closed. He died twenty-four hours later, and necropsy was refused.

CASE II: Perforated Duodenal Ulcer.—F. W. B., male, 40. Operation four days after perforation, which was minute "leaking." There was marked lymph formation over the whole of the right flank. Perforation closed, and a posterior gastro-enterostomy done. Drained, two tubes. He made a good recovery, and was discharged from hospital. Three months later he was readmitted with intestinal obstruction of four days' standing. At operation there were dense adhesions both where the tubes had been and to the abdominal sear, none elsewhere. He died the same night. None of my other cases of perforated peptic ulcers (16) have shown evidence of the formation of adhesions. They have either been closed without drainage or the tubes have been removed within forty-eight hours.

CASE III: Acute Appendicitis, Diffuse Peritonitis; Operation, Appendicectomy.—N. B. S., female, 5. Drainage through a supra-pubic stab. Tube out in forty-eight hours. Tenth day a second laparotomy on account of intestinal obstruction. Small gut greatly distended and adherent to a small residual abscess on the upper surface of the sigmoid mesentery—remote from the situation of the drainage tube. The rest of the peritoneum was clear of adhesions as far as was seen. Gut was freed and oversewn and the abscess drained for forty-eight hours. She made an uninterrupted recovery.

These three cases illustrate what I have found to be the common sites at which dense adhesions are liable to form. They point strongly to the danger of prolonged drainage.

The essential difference between an abscess cavity in the peritoneal cavity and a generalized peritonitis is that the latter has the power of isolating a foreign body by adhesions. An abscess cavity is lined by granulation tissue which has not got this power. The whole peritoneum, or a really large part

of it, cannot become an abscess cavity; the patient dies long before this point is reached.

The whole matter of length of drainage comes therefore to the question how long an inflamed peritoneum can delay its power of isolating a foreign body. The healthy peritoneum isolates the least irritating of foreign bodies in about twelve hours or less. I have never seen a diseased peritoneum which had not done so in twenty-four hours, and I find it very hard to believe that it can be delayed beyond about forty-eight hours. If you believe that this power can be delayed three or four days or longer, then for just so long is prolonged drainage defensible. We really want a pathologist with vast experience to tell us, first, what is the longest time he has seen a tube left in a living patient without its having been shut off, and secondly, what is the average time in cases of diffuse peritonitis. The latter figure should form our routine, the former our maximum, only to be used in desperate cases. To drain longer would be unjustifiable. When there is a localized abscess lined by granulation tissue the case is different; here the tube should be shortened gradually as the abscess collapses. In diffuse peritonitis it should be cut to a length, which is that of the thickness of the abdominal wall, after forty-eight hours.

The next point to be considered turns on the frequency of

residual abscesses where drainage is curtailed as to time. It is difficult to determine from so small a number of cases. My own impression from my own and from reading the notes of and seeing other cases treated by more prolonged drainage, is that they are not more frequent; drainage, however prolonged, does not eliminate the risk of residual abscess. The residual abscess is so often remote from where the tube has been that it is difficult to see how any drainage short of "kippering" the patient could eliminate it. The usual fate of a residual abscess is to resolve without interference by the surgeon. The history of appendix abscess as well as recent experience and present doctrine all combine to prove this. It was formerly the fashion to wait until an appendix abscess resolved. Quite 60 per cent. did resolve. After a period of operating on everything

it is now recognized almost universally as good practice to wait under certain defined conditions—namely, a history of longer than four days, an improving patient, a palpable decreasing tumour, and when immediate operation can be performed should the improvement not be maintained. This is most emphatically not a doctrine of waiting in the early stages of an attack of appendicitis. Most of the residual abscesses which occur after operation will disappear if the patient is watched under conditions of semi-starvation and rigid non-interference by purges, etc.; but if increasing or if reasonable suspicion exists that it is causing the formation of obstructing bands, it should be appropriately drained.

The foregoing remarks apply with equal force to the maintenance of the Fowler position, except that here it is only a comfortless position and not a dangerous complication which is at stake. Any peritoneal exudate which has not gravitated to the pelvis in forty-eight hours must be dealt with *in situ* by the peritoneum. Fortunately for the surgeon, in the majority of cases the peritoneum is capable of dealing effectively with what he leaves behind.

Acute Dilatation of Stomach.

The frequency of this condition is difficult to determine. Cases which reach the stage of exhibiting a complete clinical picture usually die whatever is done for them. On the other hand, we are hardly justified in claiming that every case whose vomiting is cured by gastric lavage is a case of acute dilatation. One is almost justified in saying that the surgeon who never sees a case treats it most efficiently. Pathologically it is a paralytic dilatation of the stomach most commonly occurring after abdominal operations, but sometimes when there is no other disease in the abdomen. Whether a mechanical factor exists after the dilatation has commenced

FIG. 1.—a, Tube; b, aponeurosis; c, muscle; d, peritoneum; e, gut in section; f, barrier of lymph separating abscess from tube; g, abscess; h, granulations adherent to f, damaged gut liable to be obstructed as h contracts.

is a matter of little but academic interest. Clinically, there are repeated large vomits and belchings of wind, relieved temporarily by the passage of a stomach tube, marked distension of the upper abdomen, chiefly to the left of the mid line, and great prostration.

Treatment.—The important thing is that further operation on the stomach is almost uniformly fatal. Repeated gastric lavage, combined with the prone position over a pillow with the head low, saves a few cases. If an anæsthetic vomiting persists for more than twenty-four hours, there is a grave suspicion that this condition is commencing, and if there is distension, eructations, and a rapid pulse, no time should be wasted in conjecture. If a stomach tube be passed it will often be found that a patient who is apparently emptying his own stomach every few minutes still has a reserve of 30 to 40 oz. of filthy fluid in it. The stomach should be gently washed out again and again with sodium bicarbonate (60 grains to the pint) through a large funnel, until the wash is clear. If the patient is greatly relieved this should be repeated every four or six hours, until the stomach contents fall to less than 4 oz. on passing the tube. All feeding by the mouth should be stopped and rectal or subcutaneous salines given. The passage of a stomach tube sounds and looks a brutal procedure; but the relief is so great that patients will often demand its repetition. Provided that the tube is soft its passage is safe where a gastro-enterostomy has been done—far safer, in fact, than leaving a dilated stomach.

Ileus Paralyticus.

This is a paralysis of the motor mechanism of the gut which may be due to (a) toxæmia, (b) over distension, (c) trauma and exposure. Most textbook descriptions advise calomel, castor, pituitrin and saline purges, etc.; eciton oil is not often advocated. Ileostomy and caecostomy are also advised.

First, ileus, apart from peritonitis, is rarely found either at second operations or *post mortem*. This means either that it is a rare condition, or that cases of it usually recover; both statements are probably true. The common finding, both at operation and *post mortem*, is a widespread plastic peritonitis, which is a mechanical bar to peristalsis; not that there is localized obstruction complete at any one point and to be relieved by operation, but, as it were, a brake applied over a considerable length of intestine. Cases diagnosed as ileus are therefore more truly described as *post-operative peritonitis*. All the cases of paralytic distension I have had the opportunity of accurately observing have been in association with peritonitis, usually primary, sometimes secondary to obstruction. When the condition of the small gut is observed during operations for appendicitis, it is in the immediate vicinity of the iliac fossa that the gut is most distended. From a consideration of the usual lie of the gut in the abdomen this means the lower third of the small intestine (Fig. 2). It is justifiable to assume that the gut dilates because it is inflamed, and that the dilated condition is the resting condition in response to inflammation. The pathological picture with which we have to deal in an ordinary case of appendicitis is therefore that the lowest coils of the ileum are inflamed and distended, and the gut progressively approaches the normal as the stomach is approached (Fig. 3). It is rational to attempt to empty this, but normally, and in fact nearly always, it empties itself. The precise action of the various methods we have at our disposal shows that the difficulties are greater than in dilated stomach.

Fig. 2.—A. n. Line of mesentery; X, portion of abdomen in which upper third of small intestine usually lies; Y, portion where middle third usually lies; Z, portion where lower third usually lies.

mediate vicinity of the iliac fossa that the gut is most distended. From a consideration of the usual lie of the gut in the abdomen this means the lower third of the small intestine (Fig. 2). It is justifiable to assume that the gut dilates because it is inflamed, and that the dilated condition is the resting condition in response to inflammation. The pathological picture with which we have to deal in an ordinary case of appendicitis is therefore that the lowest coils of the ileum are inflamed and distended, and the gut progressively approaches the normal as the stomach is approached (Fig. 3). It is rational to attempt to empty this, but normally, and in fact nearly always, it empties itself. The precise action of the various methods we have at our disposal shows that the difficulties are greater than in dilated stomach.

1. **Direct Emptying of the Dilated Gut by means of a Tube.**—This may be done at the primary operation, but patients recover without this drastic measure too often to make it part of the routine in operations for severe appendicitis. A drainage operation may be performed after the condition has been diagnosed; caecostomy, ileostomy, entero-anastomosis, all have their advocates. My own small experience of these operations is not satisfactory (two cases with two deaths after ileostomy). Theoretically, caecostomy drains the gut below an obstruction. Ileostomy is in theory sound; perhaps I have been unfortunate, but I have never

seen it save a life, and I have seen absolute rest save several lives.

2. **Measures which Depend on Stimulating the Gut.**—It must be remembered (Fig. 3) that the paralysed gut is already receiving its normal stimulus—distension—in excess and is not responding. All the measures which stimulate the gut—calomel, salines, castor oil, eserine, pituitary—are bound to act most effectively on the normal upper coils of small intestine. Whether they have any effect on the paralysed gut below is very questionable. Their effect will be to force more fluid into the distended cesspool near the ileo-caecal valve. Those who have used Moynihan's tube will know how impossible it is for force from above to empty coils of distended gut. I therefore believe that any stimulation can only add to the difficulties near the ileo-caecal valve, and until the passage of flatus indicates that the tone of the small intestine is recovering all purgation is absolutely contraindicated. The best way of restoring the tone of the gut is to give it rest by administering morphine and withholding food—the great initiator of peristalsis—until flatus is passed.

Enemas.—An enema can reach the lowest coils of the small gut, and a single effective enema may do good. If it be retained, a second or third can only add to the patient's discomfort. The bowels act because the patient is getting well. He does not get well because his bowels act. If his bowels do not act for a week and he is comfortable there is no occasion to worry. What generally happens when a patient is left alone is that he passes flatus spontaneously about the second or third day. On the fourth or fifth he has a natural call to stool and passes a profuse liquid stool; after that he can have food and a purgative. If he is distended, the effect of a single small turpentine enema may be tried; it may aid him to pass flatus or a motion. Should it be retained or returned unchanged, this must be accepted as an indication that the muscle of the small gut is not yet ready to pass on its contents; he should be left entirely alone except to give morphine if he be restless. The experiment may be repeated after twenty-four hours. Lockhart-Mummery has shown that the so-called high rectal tube, unless passed with the aid of a sigmoidoscope, coils itself up in the rectal ampulla. The cautious use of pituitary extract seems to help a little, but it should never be given in repeated doses, and it acts probably only in the cases that would have recovered without it. The important part of the treatment is to leave the patient alone, give morphine when it is called for, and restrict food without cutting down fluid.

Intestinal Obstruction.

Sometimes it is difficult to decide whether a patient is suffering from paralytic distension due to peritonitis, or from intestinal obstruction due to a band. Organization and contraction of adherent bands of lymph must take place before they can distort the intestine sufficiently to produce obstruction, and this takes six to ten days. This time is an important factor in making a diagnosis.

The cases which show evidence of ileus paralyticus are particularly prone to develop obstruction about this time. The reasons are, I think, that the cause, peritonitis, is present, that it is easy to leave an acute kink in gut which is distended, and there is no peristalsis to straighten out any such kink. It is well to be on the watch in such cases, and to waste no time in exploring again where the slightest confirmatory physical sign exists.

FIG. 3.—A, Empty, healthy small gut, readily excitable by food or purgatives; B, distended, inflamed, kinked and inexcitable gut; C, appendix—commonest primary cause; D, fluid faeces—highly toxic if under pressure; E, left alone, usually no evidence of toxæmia.

Patients who have a mechanical obstruction nearing completion suffer from attacks of spasmodic colicky pain with short intervals of relief. If this fits in with the time factor the presence of obstruction should be suspected. Visible coils of gut are almost diagnostic of obstruction, and if peristalsis is either visible or audible the diagnosis is no longer in doubt. Vomiting is a late sign of obstruction. It means that the distension has reached the upper coils of gut. It is matter for congratulation if the diagnosis is made and the second operation performed before the patient has vomited.

Lastly, though the results of an enema and the passage of flatus are strong negative evidence that obstruction is not complete, they are not absolutely so. The worst post-appendix obstruction I ever operated on had had a "good result" that morning. In this case the small gut was so distended that it blew out and burst like a bicycle tyre when the abdomen was opened.

Post-operative Peritoneal Infection.

Repeated dark vomits, distension, hiccough, and marked toxæmia, are evidence that the patient, as a whole, and his peritoneum in particular, are failing to cope with the virulence or numbers of the organism. Further operation holds out little prospect of doing any good. There is no one collection of pus that can be effectively drained. The gut is friable and will not bear the gentlest handling, and stitches will not hold if it is torn. The only chance for such patients, and it is a slender one, lies in absolute rest, morphine, and rectal or subcutaneous salines with glucose.

Remittent pyrexia should lead to examination of the abdomen, digital examination of the rectum, and examination of the bases of the lungs. If a residual abscess is diagnosed it is well to wait a little and watch progress unless the patient is going downhill. The majority get smaller and finally resolve. If the abscess gets bigger or the patient deteriorates it must be drained in the appropriate manner. It is best not to await rupture into the rectum or vagina. Such cases do better if deliberately and adequately drained.

A CASE OF PRIMARY CARCINOMA OF THE LUNG.

BY

G. S. HAYNES, M.D., AND J. F. GASKELL, M.D.,
M.R.C.P., F.R.C.P.,

ADDENBROOKE'S HOSPITAL, CAMBRIDGE.

This case was under continuous observation by one of us in the wards of Addenbrooke's Hospital for four months before death, and in the earlier stages simulated tuberculosis with somewhat interesting and rapid alterations in the physical signs. The correct diagnosis was only reached when definite enlargement of glands above the left clavicle was found to have taken place. Owing to the length of time the case was under observation it seemed to us to be worth putting on record.

Primary carcinoma of the lung is an uncommon disease. Hamman¹ states that 105 cases occurred in 46,169 autopsies, a percentage of 0.2; figures given by Ewing² show that 1.0 per cent. of primary cancers occur in the lung.

Primary growths are classified in three groups according to their origin: (1) From the bronchial epithelium; (2) from the bronchial mucous glands; (3) from the lung substance. The type of tumour found in group (1) seems to be localized to the larger bronchi and not to spread diffusely, to break down easily and form brouchiecatic cavities, being histologically essentially columnar-celled. Tumours of type (2) are characterized by abundant mucous secretion derived from the special type of cell of which the growth is composed. They also tend to be localized round the larger bronchi. The third group comprises the diffuse cancers with widespread destruction of lung tissue by rapidly spreading infiltration. The type of cell found in these varies, even in different parts of the same tumour, from columnar to flattened epithelium-like cells. The greater mass of cells are usually cubical in shape. The point of origin of tumours in the third group is difficult to determine, as their growth is rapid and diffuse. The cubical type of cell points to an origin either from the bronchioles or from the lining cells of the alveoli, whose shape often becomes cubical in collapsed lung. The matter is, however, of academic importance. Our case falls within the third group, the tumour being diffuse and the preponderating cells being cubical in type.

Clinically, carcinoma of the lung presents itself as a chronic pulmonary inflammatory disease, as a chronic pleurisy with effusion, or as a local patch of permanent consolidation; the usual diagnosis is pulmonary tuberculosis, fibroid plithisis, or unresolved pneumonia. The symptoms which suggest growth are rapid loss of weight and strength, pain, dyspnoea, and peculiarities in the physical signs, which are frequently unilateral. Pain is by no means always present, but severe continuous pain in the absence of pleurisy, or a constant boring pain with indefinite or unusual physical signs, should arouse suspicion. Fever, though always present in some degree, is usually much less than is found in tuberculosis rapidly advancing; the temperature may not rise above normal for days or even weeks. Sputum may be absent for some time, but in the later stages is frequently abundant; it is usually mixed with blood, and has been likened to currant jelly. Persistence of bloody sputum for weeks and months is very suggestive. The pleura is so commonly involved that pleural effusion is one of the chief signs of the condition; it is often smaller in amount than the physical signs would lead one to anticipate, and it is frequently tinged with blood; but the commonest cause of blood-stained pleural effusion is not malignant disease, it is tuberculosis (Horder³). Pneumothorax is a not uncommon occurrence in the course of the disease. Most of these points are illustrated in our case.

A. T. R., aged 27, a French polisher, was admitted to Addenbrooke's Hospital, Cambridge, on December 11th, 1920. He complained that for the past three weeks he had been troubled by shortness of breath, cough, and "blood spitting." He had previously had good health; he had, however, been in the army in March, 1918, for about a year, and had been in hospital for this disability he was pensioned. At the time of his discharge he had a cough, which disappeared after treatment for a few weeks in hospital.

He was a poorly nourished man, weight 7 st. 9 lb., a little dyspnoeic, not cyanosed. The physical signs were those of pleurisy, with a little effusion and patchy consolidation of the lower lobe of the right lung; the condition was thought to be tuberculous. During the first fortnight in hospital there was some loss in weight, and a rising temperature to just under 100°, but no other change. He had a little cough, with the daily expectoration of blood-stained sputum in which tubercle bacilli could not be found. Towards the end of December the patient had lost 6 lb. in weight, the evening temperature was rising to just over 100°, the pulse rate still increasing and the physical signs extending.

He was now placed on a balcony under open-air conditions, and at the end of three weeks had improved; he had regained 6 lb. in weight, there was little cough or sputum, though this was still blood-tinged; the evening temperature was not over 99° F. for fourteen days. The physical signs were much the same in the right lung; there were only occasional rhonchi in the left.

On January 25th, 1921, well marked signs of pneumothorax were observed; there was no pain or distress and the onset had evidently been insidious. A skiagram showed a right hydro-pneumothorax, and that the heart and aorta were displaced towards the right. A few days later blood-stained fluid to the amount of 4 c.cm. was withdrawn from the right thorax; the fluid was sterile and contained polymorphonuclear and mononuclear cells in equal quantity. In the middle of February the patient, who had become much emaciated, complained of constant gnawing pain in the right hip and thigh; in spite of treatment this continued almost without remission to the end.

The pneumothorax slowly disappeared, leaving the whole of the right side of the chest flat and immobile, dull to percussion, with very feeble breath sounds; the heart was displaced towards the right. Early in March enlargement of the left cervical glands was noted; they were soft, painless, and not tender; they rapidly increased in size, and those on the right side became palpable and visible. Towards the end of the month hoarseness, stridor and oedema of the face commenced and the superficial veins of the upper thorax became engorged. These signs of obstruction increased, and the patient died on April 15th, 1921. During the last eight weeks the temperature was normal or subnormal.

At the necropsy the whole of the right lung was found to be tightly adherent to the thoracic wall; the lobes were indistinguishable, almost the whole lung being involved in a hard white fibrous growth, from the cut surface of which thin white material could be easily scraped. The growth was most dense at the hilum and was found to involve the wall of the bronchus almost up to the bifurcation. The only portion of the lung comparatively normal was the extreme lateral part, which was collapsed. The left lung was entirely free from growth, and was emphysematous and congested. The left-pleural cavity contained about a pint of milky fluid, chylous in nature and probably due to involvement of the thoracic duct; the pleural walls were in a condition of gelatinous oedema. Bronchial and tracheal glands were involved on both sides, forming a continuous mass with the greatly enlarged glands in the neck. The lumen of the superior vena cava was much narrowed by constriction. On the upper surface of the liver were four small nodules of growth; two of these were half an inch across and two less. The posterior abdominal glands were enlarged, but none were more than half an inch in diameter; on section they showed a similar appearance to that of the main growth.

Microscopically the lung substance is replaced by a mass of cubical cells which, though in most places irregularly arranged,

here and there show attempts at a palisade-like arrangement; they contain very little protoplasm. The original structure of the lung is only indicated by still surviving bronchial cartilage belonging to the larger bronchi, and an occasional small group of glands belonging to the bronchial wall. Fairly numerous blood vessels with well-formed walls are present which may be still surviving vessels of the lung. In many regions marked degeneration is taking place with disintegration of nuclei and general loss of staining power. In these areas accumulations of fat are present. Fat is also present in considerable quantities in tissue which appears to be fibrous in nature, rapidly degenerating and undergoing invasion by columns of cells. The nature of the tumour is carcinoma of the cubical-cell type which has probably grown from the terminations of the bronchioles. The secondary nodules in the liver are very similar except that much more fibrous tissue stroma is present, the cells tend to more regular palisade arrangement, and are in places more of a columnar type. The tumour is not sharply marked off from the liver, which is being rapidly invaded at the growing edge. Isolated batches of liver cells can still be identified here in the fibrous stroma; farther in the nodule they have become reduced to little masses of bile only.

The chief points of interest in this case are: the age of the patient, 27 years; the duration of symptoms, five months; the similarity to tuberculosis of the lungs—for example, wasting, fever, cough, haemoptysis, pleural effusion, and pneumothorax; the temporary improvement under open-air treatment, due to the elimination of secondary infection; the total absence of pain; the involvement of one lung only, and, finally, the rapid enlargement of the mediastinal and cervical glands. The right lung was extensively involved while the left lung was unaffected, but yet the left cervical glands were considerably more affected than the right, the path of spread being probably along the course of the thoracic duct.

BLINDNESS AS AN IMMEDIATE SEQUELA OF INFLUENZA: RECOVERY.

BY

STANLEY E. DENYER, C.M.G., M.D. CANB.,
F.R.C.S. (ENG.), D.P.H.,

ACTING PHYSICIAN, HULL ROYAL INFIRMARY.

THE following case well exemplifies the conditions described by Jelliffe and White as quoted below. The patient, a young woman aged 17, was, during convalescence from influenza, attacked with papillitis, which was accompanied by blindness of rapid onset and frontal and temporal pain. The sight was gradually recovered in the course of three or four weeks. There was no evidence of cerebral tumour or abscess, or of syphilis, and the Wassermann reaction of the cerebro-spinal fluid was negative.

In view of the large number of cases of influenza at present occurring, the case may be of interest, and useful in that it shows that the prognosis of the blindness is good.

A girl, aged 17, was admitted into the Hull Royal Infirmary on January 4th, 1922, under my care, from the ophthalmic surgeon's out-patient department, by Dr. Bainbridge, who sent the patient in for medical treatment with a diagnosis of "papillitis." He reported the eye condition as follows: Pupils widely dilated, but active; no pain on moving eyes by palpation; consensual reaction present; periphery of fundus not much affected; discs swollen; edge blurred, veins dilated.

The history was that three weeks before admission she was taken ill with influenza, and was in bed for one week. There was no cough. A week later her eyes and eyelids hurt her, and "a dark mist came over her eyes." She could not see to read in bad light or good. In the ward we found that she was blind in the right eye, with no perception of light. With the left eye she could see fingers at one foot. On ophthalmoscopic examination there was marked optic neuritis (papillitis) of both eyes. She had a headache (frontal and left temporal region) which had lasted fourteen days. There was no discharge from the ears, and the right and left drums were normal; in the right ear a whisper was heard at seven feet, with the left conversational voice at five feet only. Bone conduction was slightly diminished in the left ear. There was no tenderness over either mastoid, and no discharge from the nose.

Dr. Ritchie Rodger reported that he could not find anything to suggest ear, nose, or throat origin. The heart was not enlarged; the first and second sounds were loud, and there was no bruit. Lungs and abdomen showed nothing abnormal. The urine, specific gravity 1030, was acid, and contained a trace of albumin; the daily amount was thirty-six ounces; urea, eight grains per ounce. Blood pressure, 55 mm. Hg.

Central Nervous System.—No Kernig's sign, but slight tension on hamstrings of both legs; knee-jerks normal; Babinski's sign not

present; no ankle clonus; no inco-ordination. Mentally decidedly dull, answers questions slowly.

A swab taken from the nasopharynx, from which there was a slight discharge, on culture showed pneumococci, staphylococci, and *Micrococcus catarrhalis*.

Treatment.

The patient was given a farinaceous diet, and milk and fish. The following mixture was prescribed: Potassium citrate gr. 5, liq. ammon. acet. in 15, hexamine gr. 5, ag. ad 1 oz.; to be taken four times a day and followed by barley water 2 oz. One hot pack to be given.

On January 7th lumbar puncture yielded 1.5 c.cm. clear cerebro-spinal fluid; it contained a few lymphocytes but no organisms on culture.

January 9th. No headache; can see hand with right eye.

January 10th. Sees fingers with right eye at 2 feet; with left eye at 7 feet. No headache; is taking food well. There was now no tension on hamstrings; no ankle clonus; no anaesthesia; no inco-ordination; knee-jerks normal; optic neuritis was still present (oedema of discs).

January 11th. No headache; vision the same; 10 c.cm. clear cerebro-spinal fluid withdrawn by lumbar puncture was negative to Wassermann test.

January 13th. Blood pressure 95 mm. Hg; optic discs slightly improved. Pneumococci vaccine 1 million given.

January 20th. Ophthalmic surgeon's report: She can now read ordinary print; optic discs nearly normal. Right fundus, veins dilated, otherwise nearly normal. Left fundus, disc normal. There was no albumin in the urine. Blood pressure, 102 mm. Hg. January 23rd. Can read without pain or headache; she feels quite well; oedema of legs and albumin have disappeared.

January 27th. She feels quite well, and is getting up. The ophthalmic surgeon reported: Slight swelling of right optic disc and veins moderately dilated. R.V. 6.25; with -1 eye axis 90 vision equals 6.18. Left eye: Fundus normal, vision 6.12; emmetropic. In the ward she was found to be able to read ordinary small print quite well, in not too good a light. She stated that she felt nothing wrong with her head.

De Schweinitz, in his *Diseases of the Eye* (ninth edition), says: "In addition to the intracranial causes of papillitis this phenomenon may arise from a general infection." To this form Uthoff gives the name "infectious optic neuritis." According to this observer it should be differentiated from those cases which are caused by orbital, intra-ocular, or intracranial lesions, and may be caused by any of the following diseases, placed in order of their frequency: Influenza, syphilis, rheumatism, malaria, typhus fever, measles, whooping-cough, diphtheria, polynenitis, small-pox, beri-beri, erysipelas, scarlet fever, tuberculosis, typhoid fever, gonorrhoea, relapsing fever.

The neuritis may manifest itself as a papillitis or as a retrobulbar neuritis, and Uthoff thinks that the optic nerve conditions are most apt to arise during the stage of convalescence and are probably due to the action of toxins and not directly due to micro-organisms.

Again, Jelliffe and White, in *Diseases of the Nervous System* (third edition), say: "Acute axial neuritis occurs usually in young adults, 12 to 24 years of age, more particularly women; frontal or temporal headache, or deep pain in orbit, made worse by pressure or by movements of the eyeballs; loss of sight is rapid, reaching a maximum in five days, and often is so severe that the patient can just count fingers at fifteen feet or is blind."

After the acute stage is over there is gradual recovery of sight. For a more detailed account see article by Jelliffe, "Nervous and mental involvements of influenza," *New York Medical Journal*, November, 1918.

I should like to draw attention to the condition of "slight tension on the hamstrings of both legs." I have noticed it several times in cases where I was of the opinion that an infection had become generalized. It is not Kernig's sign, but approaching it. It is probably due to an excess of toxin in the blood; possibly it may be due to organisms in the blood, but this is, I think, unlikely, as cases in which I have noticed it have in some instances cleared up too rapidly. There is no head retraction or even stiffness or pain on twisting the head or neck in any direction. Also if in a case showing it the test be made daily it will be found gradually to get less in cases that are improving.

A patient showing this sign I was asked to see some months ago was a child, aged 6 years, with acute abdominal pain and vomiting, accompanied by diarrhoea and fever. I decided against any operative interference, chiefly on this sign. The abdomen was tender all over and slightly rigid. The fact that there was slight tension on the hamstrings, in my opinion, to a generalized infection. In appendicitis the same condition is sometimes seen, but only in one leg, or it is much more marked in one leg—namely, the right. In the case of this child I thought that there was a slight early

peritonitis, or a condition which is a prelude to that, possibly pneumococcal. The condition cleared up in twenty-four hours on a powder of calomel gr. 1/8, sodium salicylate gr. 2, bismuth carbonate gr. 3. The implication of the nervous system is probably more intense in such infections.

The Lettsomian Lectures

ON

AMOEBIIC LIVER ABSCESS.

DELIVERED BEFORE THE MEDICAL SOCIETY OF LONDON

BY

SIR LEONARD ROGERS, C.I.E., M.D., F.R.S.

[Abstract.]

LECTURE I.—ETIOLOGY AND PATHOLOGY.

SIR LEONARD ROGERS began by saying that when he received the invitation to deliver the Lettsomian Lectures he cast about in his mind for a subject from among the many diseases which he had been investigating during his twenty-seven years of research in India. In view of the fact that he had been awarded the Fothergillian medal of the society for his work on amoebic diseases, he came to the conclusion that he might suitably deal with amoebic hepatitis, more especially as the late Dr. Sandwith had ably dealt with dysentery in the Lettsomian Lectures of 1914. The present course, therefore, would be complementary to that given by Dr. Sandwith, and would deal with that phase of amoebic disease investigated at Calcutta during a period when the knowledge of hepatitis generally had made great advances. The work on the liver had been one of the most significant episodes in recent tropical medicine, although perhaps less dramatic than some discoveries, because more gradual.

A Review of Progress.

At the beginning of the present century there was a good deal of confusion with regard to the relationship between dysentery and large single tropical liver abscess. The confusion was due to ignorance of the fact that there were two great classes of dysentery which, until recently, had been regarded as one definite disease. Those whose experience was in countries where the bacillary form prevailed denied its relation to liver abscess, while in Egypt and India, where amoebic dysentery was known to be common, observers had noted a relation. It was now understood that the prevailing type of dysentery in temperate climates was bacillary. In John Hunter's account of dysentery in the army in Jamaica in 1788 he did not mention liver abscess, and considered the dysentery to be the same as that described by Sydenham as so prevalent in London in 1779-80. Recent investigation showed that to this day the bacillary type prevailed in Indian gaoles, where the amoebic form was comparatively rare. In the *Researches into the Causes, Nature, and Treatment of the More Prevalent Diseases of India and of Warm Climates Generally*, by James Annesley, of the Madras Medical Establishment, published in two volumes by the India Office in 1828, it was clearly stated that liver abscess was secondary to dysentery. It was quite certain from these finely produced and illustrated volumes that amoebic dysentery was common in Madras early in the nineteenth century.

In the first three editions of his classical work on tropical diseases Manson described dysentery as a single entity; he pointed out that the term probably included a group of diseases, but that up to then the claims for different causative agents, whether bacterial or protozoan, were far from having been established. The confusion at the beginning of the present century was well illustrated in the contradictory nature of articles on the subject in the first edition of Allbutt's *System of Medicine*. Altogether, it was not surprising that the amoeba was not accepted as the cause of the disease. Manson, in his early edition, stated that amoebae were present in more than half his cases, but this did not convince him of their causative powers. At the annual meeting of the British Medical Association in 1902 Andrew Duncan, who had then recently retired from the Indian Medical Service, opened a discussion on dysentery, and advanced the view that the amoeba had nothing to do with dysentery in any country as a causative agent.¹ In Duncan's view, large tropical liver

abscess did not bear any specific relation to antecedent dysenteries, although small multiple abscesses did. Very similar views were also expressed at this time in a short editorial note in the *Indian Medical Gazette*. In spite of the valuable work of several observers, especially Councilman and Kartulis, medical opinion at this time was against the theory of amoebic causation.

Constant Presence of Amoebae.

Sir Leonard Rogers went on to say that he had published his first paper on dysentery in 1902. It was based on two years' research he had conducted in Calcutta between April, 1900, and the end of 1902, making use of all the clinical and *post-mortem* material he could obtain. The first point he had set out to determine was the frequency with which living amoebae might be found in large tropical liver abscess. It was easy to detect the amoebae *post mortem* in the walls by examining scrapings under the microscope, but much more difficult to detect them in the thick pus of such abscesses. In order to get a larger range of cases than was afforded by *post-mortem* examinations he arranged with his surgical colleagues, when they opened a liver abscess, to place some of the thick pus in one sterile test tube, and in another the light scrapings from the wall of the cavity. Out of some 18 cases examined in this way, he found the amoeba in the pus in four, but in the scrapings of the wall he found it in every case except one. In 20 cases examined *post mortem* he again found the amoeba in the wall in every case except one, the exception being an instance in which the abscess had been opened and drained for fourteen days before the patient died. From this he concluded that amoebae were practically invariably present, a fact which he had verified in scores of later cases, the only exceptions being small and encysted abscesses in which the amoebae seemed to have died out.

Usual Sterility as regards Bacteria.

He turned next to the question of the frequency of pus-forming bacteria in large tropical abscess. Out of 24 cases in which cultures were made from the pus taken in sterile test tubes at the time of operation, 15, or 62 per cent., were sterile. The *post-mortem* examinations told the same story. In three out of five unopened abscesses found *post mortem* there were no bacteria. In a later series of observations, out of a large number of consecutive cases he found 86 per cent. sterile when first opened. It was clear that the great majority of such abscesses were free from bacteria that could be cultivated, although few such abscesses remained sterile in a tropical climate after opening and drainage. His conclusion was that not only were amoebae constantly present, but other causal bacterial organisms were constantly absent. This indicated that *Entamoeba histolytica* was the causative organism in these cases of liver abscess.

The Antecedent Dysentery.

The striking fact had not been explained that the proportion of cases of liver abscess to cases of dysentery in the British Army in India was 1 to 5 or 1 to 7, while in Indian gaoles it was one to several hundred. But if the prevailing type of dysentery was amoebic in the army, and bacillary in the gaoles, the problem was solved; this was now known to be the case.

It had next to be determined what was the frequency of association between any form of dysentery and liver abscess. Among the cases of liver abscess which he had tabulated for the purpose of the lecture, in four there was no history of dysentery, but even in these, dysenteric ulcers were found *post mortem*, proving that the absence of clinical signs of previous dysentery did not exclude the presence of amoebic ulcers in the large bowel. In three other cases there had been a history of dysentery and no ulcers or scars were found *post mortem*, but only slight congestion; thus it was possible for antecedent dysentery to clear up without necessarily involving any ulceration before the patient died of liver abscess. In order to get accurate data it was essential to obtain both clinical and *post-mortem* records, and even then it was possible that a mild attack of bowel trouble might be overlooked clinically and leave no *post-mortem* evidences. The cases shown in his tables in which the clinical and *post-mortem* records were complete numbered 24, and in 23 (or over 95 per cent.) there were either clinical or *post-mortem* evidences of dysentery, while in 14 (or 58 per cent.) there were both clinical and *post-mortem* evidences. On adding certain older records which clinically were less complete, only

¹ BRITISH MEDICAL JOURNAL, 1902, vol. ii.

9 per cent. failed to give a positive result either clinically or post-mortem. He concluded that amoebic dysenteric ulceration of the large bowel, often of a latent nature, always preceded the formation of large tropical liver abscess.

It was clear that the conclusions he had reached at the end of the first two years of his investigation were diametrically opposed to those of the distinguished tropical physician who opened the debate on dysentery at the annual meeting of the British Medical Association in 1902. In the following year, while at home on leave, he met Andrew Duncan, who with the utmost candour volunteered the statement that the paper recording these new investigations had completely upset almost everything he had said in that opening address. The paper, however, contained one error, corrected the following year, in its assumption that small multiple abscesses belonged to another category in respect to causation. Whatever the explanation might be, he was now certain that the majority of small multiple liver abscesses seen in Calcutta were amoebic in origin.

In 1913 he was able to supplement the data recorded in 1902 by an analysis of the results of forty-five necropsies which he had performed during the previous ten years: there was evidence of active amoebic dysentery in 78 per cent., and scars of former dysenteric lesions in 20 per cent. more, leaving only one case with no post-mortem evidence of dysentery. He recorded at the same time an analysis of careful clinical records of fifty cases of liver abscess during nine years, with a history of dysentery in 72 per cent., and of diarrhoea in 14 per cent., leaving only 14 per cent. with no history of lesions of the bowels.

Lesions of the Bowel in Relation to Type of Liver Abscess.

A close examination of the distribution and extent of the bowel lesions in various conditions threw much light upon this matter. The positions and extent of the lesions, from the lower ileum down to the rectum, as found in 96 consecutive post-mortem examinations, had been examined. In a number of cases of acute bacillary dysentery of less than one month's duration the whole length of the bowel was affected, including generally the lower part of the ileum. In a group of chronic bacillary dysenteries of a month or more in duration all except one showed the lesions limited to the lower half or two-thirds of the bowel. In acute amoebic dysentery, instead of continuous lesions, scattered lesions were found; they were very extensive, the large patches being met with throughout the greater length of the bowel. In chronic cases the lesions were less extensive. In five cases liver abscesses were present—in four of the five multiple small abscesses, and in the other a single small abscess: in all these cases the bowel lesions were extensive. In only one case—a case unusual in its clinical features—was there an exception to the rule that in multiple small liver abscesses there were very extensive lesions through nearly the whole length of the bowel. In cases of large liver abscess the lesions were less extensive; in some cases they were limited to the caecum, but in others they extended down to the ascending colon. In 13 out of 36 cases the lesions were absolutely limited to the caecum, and in 23 they were within narrow limits or there were only scars of old lesions which would not have given rise to any clinical symptoms of dysentery. In all these cases the dysentery was absolutely latent. Thus there was forthcoming an explanation of the former great stumbling-block to the recognition of tropical liver abscess as always secondary to dysentery—namely, the absence of clinical signs of that disease in a large number of patients suffering from the liver affection.

The black sloughs passed in the stools were absolutely diagnostic of amoebic dysentery, but beyond the ulcers the bowel in these cases was healthy. The appearance was very different in bacillary dysentery where, in the whole length of the bowel, there was no healthy part left.

Large Single Liver Abscess.

He dealt next with the method of formation of large single liver abscess. It was generally agreed that amoebae passed from the bowel wall to the liver through the portal vein. The earliest stage of small multiple abscesses of the liver was inflammation with clotting in the branches of the portal vein, which was followed by softening of the thin walls of the blood vessels and extension of the inflammatory process to the liver parenchyma. He believed the addition of a bacillary infection greatly assisted the breaking down of the vein walls. When multiple small abscesses arose in the liver as the result

of a pure amoebic infection secondary to sloughing dysentery, the protozoan organisms had reached the liver in enormous numbers. The question of how one or more large abscesses developed as a result of portal infection raised other considerations. In the early stage of his work he was inclined to think that the frequency with which large abscesses occurred in the upper part of the liver, and the fact that in acute amoebic dysentery the protozoan organism frequently penetrated the whole thickness of the bowel wall, suggested the possibility that it passed in the lymph flow. It was, however, possible for liver abscess to be formed by direct extension from the bowel to the liver. Examination of microscopical sections of the walls convinced him that the abscesses were really formed within the liver, and not between it and the diaphragm. It appeared that the abscess, having once originated, developed within the organ. The single liver abscesses were seldom found in sloughing dysentery. It was evident that the development of large single abscesses as a class could not be explained save as due to infection from the bowel through the portal vein. It was necessary, however, to look to another and intermediate stage to explain the ultimate development of the fibrous-walled large abscess, which, however, was not very commonly met with. In the case of large ragged cavities without well-defined walls there was no definite limiting membrane, but the tissues around the irregular cavity were infiltrated by pus. Examination of microscopical sections demonstrated that the process was extending from the central cavity along the veins in which softening and clotting were taking place; in such cases numerous amoebae were present, but in the great majority of cases no bacteria. It was clear that amoebae might reach the liver in large numbers without suppuration in the organ necessarily taking place.

Taking all these facts into consideration, he supposed that in slight or latent amoebic colitis, from which large amoebic abscesses usually resulted, comparatively few amoebae reached the liver, the vast majority undergoing degeneration in the vessels without being able to escape unless there was damage to the walls. In that case only a presuppurative amoebic hepatitis occurred. When the amoebae happened to reach some part of the liver in such numbers as to cause clotting of several contiguous small veins so as to interfere with the blood supply, and produce simple necrosis, allowing the escape of the amoebae into the soft tissues, an abscess resulted. The abscess continued to develop in concentric circles until, if the patient survived long enough, a fibrous capsule made its appearance, and the process then only went on by expansion of the cavity, without further destruction of tissue. Almost all forms of liver abscess were due to pure amoebic infections from the bowel, through the portal vein: the number of amoebae varied. Whether or not an amoebic hepatitis went on to suppuration must often be in the balance, so that such causes as chills and alcoholism might easily precipitate the formation of an abscess, and early treatment avert it. Amoebic liver abscess was now much more easily preventable and curable than it was a few years ago, and future investigators would have little chance of obtaining such material as he had had in past years.

“My conclusions, which are now in agreement with those of more recent observers too numerous to mention, may be briefly summarized. The affection formerly known as tropical liver abscess, both in the acute multiple small form and the chronic large single form, is produced by infection through the portal vein with the *Entamoeba histolytica*, only occasionally assisted by bacteria, and is always secondary to antecedent amoebic ulceration of the large bowel, which is clinically active and acute in the multiple variety, but usually completely latent clinically in the more chronic single form, while such abscesses never occur in relation to bacillary dysentery. These conclusions are a great advance on the view generally accepted two decades ago.”

THE 5th Cuban National Medical Congress, held at Havana, was attended by more than 1,500 medical practitioners. It was divided into eight sections, of which five were devoted to medical and surgical subjects, one to pharmacy, one to odontology, and one to veterinary medicine.

It is announced that the sum of 1,323,000 dollars is to be available from the Sterling funds for the erection of a new building for the Yale medical school, to be known as the Sterling Hall of Medicine. This building will contain a library, a lecture hall, administrative offices, rooms for the teaching staff, and laboratories, with an animal house and a power house adjoining.

DIAGNOSIS OF INCIPIENT ACUTE APPENDICITIS.

PART from the general desirability of making an early and accurate diagnosis, it became a matter of military necessity in 1917 and 1918 to avoid operation in non-urgent conditions other than wound casualties. The problem had become more acute in the summer and autumn of 1918, owing to the influx of cases of epidemic influenza of the abdominal type, which, in the early stages, presented signs simulating appendicitis. In the course of many observations in a general hospital of the British Expeditionary Force, I came to rely on a sign which I believe to be unequivocal; if present, operation is unavoidable.

This sign is observed, of course, only in the earliest stage: the patient complains of abdominal pain, particularly referred to the epigastrium; he looks ill and is generally vomiting; the decubitus is dorsal. Examination of the abdomen reveals, in the upper left epigastric region, skin hyperaesthesia and intense tenderness, with tonic rigidity of the left half of the uppermost segment of the left rectus abdominis muscle. On the contrary, there is no tenderness or muscle rigidity over the right iliac fossa. Three or four hours later, there is a commencement of slight pain, tenderness and rigidity in the region usually described, if one elects to wait so long.

On opening the abdomen one finds a process of great omentum approaching, applied to, or actually wrapped around, an acutely inflamed appendix, according to the time which has elapsed since the appearance of the epigastric distress. On account of this phenomenon I have been accustomed to speak of the epigastric syndrome as the "collision-mat sign"—a naval analogy, the omentum being applied to the threatened perforation much as a collision mat is placed over a leak in a warship's hull.

Whether or not this sign occurs in every case of acute appendicitis I cannot say, but I am persuaded that it does become manifest in every case calling for early operation, which, after all, is the practical point. Furthermore, in cases where operation for one reason or another had been delayed until gangrene of the appendix had set in, a history of nausea and vomiting, together with epigastric pain, was generally elicited.

As to the etiology, I formed at first a rough working hypothesis that sickness and pain were due to the drag on the stomach produced by the rapid migration of the great omentum into the right iliac fossa, but it is much more probable that these symptoms are to be explained by pain referred along the great omentum to the stomach in virtue of the development of the great omentum from the primitive mesogaster.

This sign is seldom, if ever, to be noted in patients admitted to a civil hospital, since admission is rarely sought in the earliest stage; its utility, therefore, is that it assists the usual medical attendant to recognize, at the very beginning, the case of acute appendicitis which will certainly call for operative measures, and that as speedily as possible.

ROBERT M. ROWE, M.A., M.D., F.R.C.S. Eng.,
Surgeon, Out patient Department, French
Hospital, London.

EARLY SYPHILIS OF THE PROSTATE.

ACCORDING to Loyd Thompson¹ only 24 cases supposed to be siphilis of the prostate have been recorded in the literature, and of these only 12 are accepted as authentic. Of the 12 cases only two relate to an implication in the early stage—ne was due to a direct extension from a primary sore which had become phagedaenic (Ricord), and the other was possibly genuine metastatic infection, though the description of the case is meagre (Portillo).

The case here recorded is unique because the patient has never had gonorrhoea or even sexual connexion. In most of the cases of a gummatous prostatitis it is extremely difficult to rule out a possible gonococcal lesion. The patient, a man aged 28, presented himself with a hypertrophic clauere over the right parietal bone. The infection was conveyed, in my opinion, from wearing a hired wig. The body was covered with a diffuse leucular syphilide, and the patient complained of bad headaches and pains in the bones and joints, and he was much troubled with acute indigestion: I timed the infection to have occurred fourteen weeks before I first saw him.

On asking him to pass water I found that a bead or two of pus appeared with the last few drops, a condition the patient

had noticed for the previous fortnight. There was never any blood or meatal discharge, but the urine contained threads and the patient always had the desire to micturate again when he had just finished. On examining the urethra I found acute inflammation of the prostatic portion, which was most marked around the open prostatic ducts. The mucous membrane bled easily. Rectal examination revealed the right lobe of the prostate swollen to the size of a hen's egg. The outline was uneven, the consistency was irregular, being soft in some places and hard in others; in fact a hard band seemed to cut the lobe longitudinally into two soft masses.

Under four intravenous injections of arseno-benzene both the urethra and prostate were restored to their normal condition.

J. E. R. McDONAGH, F.R.C.S.

INFLUENZA (?) ACCOMPANIED BY CONVULSION.

AT 3 a.m. on January 26th, 1922, I was called to see F. T., a man aged 38, and found him propped up in bed, unconscious. The history was that he had never had any serious illness, but that for the last three days he had suffered from a cold, for which he did not go to bed or give up at all as his wife was expecting to be confined. He had gone to sleep as usual the previous evening; on waking at 2 a.m. his wife found his face and chest wet with cold sweat, and he did not answer when she spoke to him. He seemed to be choking; with the help of friends he was raised to a sitting position in bed, which eased the breathing. When I saw him his limbs were rigid, the arms were flexed at the elbow, and the fingers bent into the palms of the hands. The pupils were equal and slightly dilated, the eyeballs rolling upwards on raising the upper eyelid. There was slight gritting of the teeth, but the tongue was not bitten; respirations were slow but not stertorous, and the face was cyanosed; the temperature was normal. He remained in this condition for four hours, when the rigidity gradually passed off and consciousness returned. At 10 a.m. the only sign of meningeal irritation—supposing that to be the pathological factor—was a certain amount of slowness in speech and perception. There was no paralysis, and recovery was rapid and complete.

Incidentally the shock caused his wife to be so deaf for a time that she did not hear unless spoken to very loudly, but this condition passed off in six hours. After the shock she received at 2 a.m. she found no more signs of life in the foetus *in utero*, and on January 29th was delivered of a full-grown child which had every appearance of having been dead for a few days.

MALLET FINGER.

DR LAIRD's excellent radiographs of a case of "mallet finger" in the BRITISH MEDICAL JOURNAL of January 21st, illustrates a fairly common if not usual condition in this injury. I have only seen one case in which the small fragment of bone was not present. I have shown several similar radiographs at the Reading Pathological Society during the last ten years. I think Dr. Laird will find the characteristic detachment of a fragment of bone, where the insertion of the exterior tendon is torn off the phalanx, is well known to radiologists and surgeons.

Some years ago I gave Mr. Warren Low a similar radiograph; the injury at that time was well known to him, and he wanted a radiograph of it. The way this injury was produced in Dr. Laird's case was unusual and interesting.

Commonly a blow at the end of the finger, as from striking a door in the dark with the fingers extended, is the cause of the trouble. When not recognized and treated it produces a characteristic deformity.

Reading.

W. J. FOSTER, F.R.C.S.

THE Cox-Cavendish Electrical Company has issued a new edition of its catalogue of x-ray and electro-medical apparatus. It fills 340 pages, is freely illustrated, and divided into sections. Special attention is directed to the "Plurostat" earth-free universal apparatus. Inspection of the volume affords a good indication of the many activities of the company. A copy will, we are informed, be forwarded to readers of this JOURNAL on application to the company, which has show-rooms at 105, Great Portland Street, London, W.1, and 15, Hanover Street, Edinburgh.

Reports of Societies.

THE TREATMENT OF GASTRIC ULCER.

At a meeting of the Royal Society of Medicine on February 2nd a discussion took place on the treatment of gastric ulcer, following upon the discussion on diagnosis held a week previously and reported in the last issue. The chair was taken by Dr. G. NEWTON PITT, and the discussion was opened by Sir W. HALE-WHITE, whose paper is printed at page 214.

Sir BRIDGLEY MORRIS, who followed, said that with almost everything which had been advanced by Sir William Hale-White he found himself in complete agreement. He would say frankly that there was no clinician in the world who, basing his opinion upon clinical evidences alone, could say with confidence that a gastric ulcer was present. By only two methods could a certain diagnosis of gastric ulcer be made: one by the radiographer inspecting the stomach after a bismuth meal, the other by the surgeon on removing the curtain of the anterior abdominal wall. By taking such a standpoint all statistics relating to gastric ulcer were vitiated, because so many other conditions had been called gastric ulcer and had been treated medically or surgically for that condition. Records of hundreds of cases were published by physicians in favour of a certain line of medical treatment, but unless there was correct diagnosis to start with, no reliance could be placed upon their conclusions. Mistakes in diagnosis upset considerably the work of the surgeon. He was sorry to say that there were still surgeons who operated upon the diagnosis of a physician. Unless the diagnosis was confirmed at the time the operation was done no operation dealing directly with the stomach was permissible. The disasters which occurred were attributed to the inefficiency of the surgical technique for dealing with gastric ulcer; this was quite true if the "gastric ulcer" was situated in the colon or the gall bladder, or in the uterus where a foetus was developing! It should be clear that when gastric ulcer was spoken of what was meant was a definite structural lesion having its origin and location in the stomach. Such a gastric ulcer ought to be cured by medical treatment. It was because medical treatment was so disastrously inefficient in this and every country that the surgeon was called in; partly also because the rich would not bother to spend the time required for the treatment, and the poor did not have accommodation, so that out-patients were given bottles of medicine and then went home and ate pickled herrings. If serious and protracted medical treatment were carried out and given its fair chance gastric ulcers should be healed.

When reluctantly the surgeon came to operate—reluctantly because every surgeon was a physician engaged in surgical practice, and would rather heal his patients without surgery if he could—he had a considerable choice of procedures. When there were many alternative procedures in surgery it meant that none of them reached the standard of immediate success and protracted relief of symptoms. The history of the surgical treatment of gastric ulcer was a little bewildering. It began with the performance of gastro-enterostomy in cases of obstructive lesion. The operation acted like a charm. Everybody had seen veritable resurrections. This acted as a decoy for some other dyspeptic. If this other dyspeptic was operated on in the absence of gastric ulcer he—he used the masculine pronoun because gastric ulcer was twice as frequent in men as in women—became one of the disastrous cases of which he had just spoken. If operation were performed in cases in which the lesion did not form an obstruction the immediate results were sometimes good, sometimes indifferent, sometimes bad. They were good in those cases in which there was a pyloric spasm, causing six-hour retention of food. Gastro-enterostomy was really a mechanical operation, relieving the retention from which the patient was suffering. The after-history of patients on whom gastro-enterostomy was done showed that a certain number got well, others complained of this, that, and the other, or came back for a second operation. He had seen new gastric ulcers develop and perforate in two patients on whom gastro-enterostomy had previously been performed. When these various unfavourable factors were assessed—when it was remembered that gastro-enterostomy frequently did not give permanent relief, that a gastric ulcer could develop subsequently and perforate, that gastric ulcer might develop into carcinoma, and that gastro-jejunal ulcer followed in a certain percentage

of cases—it would be seen that the mortality of gastro-enterostomy for gastric ulcer made the operation four or five times as dangerous as gastrectomy. Dr. Mayo's son-in-law, Dr. Balfour, of Rochester, Minnesota, U.S.A., had introduced a method of canterization of the ulcer and gastro-enterostomy. It was an excellent operation, but the mortality was as great as that of gastrectomy.

To cut a long story short, he himself came to the conclusion that the only operation which was worth while in the great majority of cases was partial gastrectomy. Even if the ulcer was small and away from the pylorus, he still practised that method. In only one case out of 118 had he been required to do a secondary operation, and that was when he had left a long loop between the stomach and jejunum. Now he swept the jejunum straight across, just below the duodeno-jejunal flexure, leaving no loop, and put the proximal part of the jejunum up against the greater curvature of the stomach. The only case which could be called unsuccessful was that of a girl, with an ulcer on the lesser curvature of the stomach, and from whose right iliac fossa he had removed a mass of tuberculous glands. That girl had attacks of diarrhoea, which might be due to the operation, but on the other hand might be due to tuberculous disease of the intestine. When gastrectomy was performed, there was an end of the matter; the surgeon never saw his patient again, except when he came to express his gratitude. He had come most confidently to the conclusion that in the vast majority of cases, whenever possible, a gastrectomy should be done, but it should be done only after the most careful preparation, and with infinite care and gentleness and with the most painstaking attention to detail. There was no need to hurry over it, and when it was finished the surgeon had the pleasant feeling that it was impossible for anything to go wrong. He gave to the Cambridge Meeting of the British Medical Association in July, 1920, his statistics up to that time. He had then done 80 gastrectomies for gastric ulcer and had had 2 deaths; he had now done 118, and the deaths still only numbered 2. At Cambridge he reported 563 operations for duodenal ulcer, with 3 deaths; he had now done 651, with no more deaths. He was beginning to get rather anxious about every patient who came in, wondering when the average mortality would assert itself. He repeated that no pre-operative diagnosis could be held valid. If the ulcer was really there it must be dealt with radically. The immediate recovery after this operation was extremely satisfactory; the ultimate recovery was secured in a way which no other surgical procedure could guarantee.

Mr. JAMES SHERRIN thought that while it was difficult to draw a line between acute and chronic ulcer, it was convenient to retain those terms. The acute gastric ulcer, unless it went on to perforation, never required direct operative treatment of the stomach. Chronic ulcer—by which he meant an ulcer more often met with in men than in women, which recurred from time to time, leaving the patient perfectly well in the intervals—in a large proportion of cases, at any rate in hospital practice, did require treatment by operation. That acute ulcers, which were usually multiple, resulted from infection he believed to be proved, and if the cause could be removed and suitable medical treatment adopted, the ulcer healed, and the patient remained well without surgical interference. If relapses occurred after efficient medical treatment, including rest in bed, the case should be considered surgically, and, of course, on perforation, immediate surgical measures were called for, but the procedure was simple, the opening should be closed, gastro-jejunostomy had no place in the treatment of acute ulcer of the stomach. An ulcer which perforated, however, was as a rule chronic. Among 360 cases of perforated gastric ulcer at the London Hospital treated by operation, only 87 were of the acute variety; the large majority were chronic ulcers which spread rapidly. When an ulcer reached its chronic stage he was not convinced of its curability apart from operation. The fact that a chronic ulcer was undoubtedly a precancerous condition should be borne in mind, and operation should include removal of the ulcer in some way, in view of its possible malignancy. He appreciated Balfour's method of destruction with the canterizer and gastro-enterostomy in the case of small free ulcers; the majority of others, he thought, were best treated by partial gastrectomy. The occurrence of stricture in the stomach or pylorus did not call for any difference in procedure; the condition of the ulcer, and not its mechanical results, should be the determining factor in treatment. After an operation it was always necessary to impress upon the patient the fact that the

physiological state of affairs was not what it was before operation, and that for three months at least he must take food which would not irritate the jejunum. With the earlier recognition of the cause of the trouble they all hoped that the need for operation would be avoided, for although the operation restored the patient to health, it altered very materially his physiology of digestion.

Sir W. H. WILLCOX stated that it was difficult to formulate rules for the treatment of gastric ulcer cases, because every case presented individual features with regard to its history and clinical symptoms. Except in those very acute cases involving perforation or almost complete pyloric obstruction, where immediate surgical measures were imperative, it might be accepted that a careful course of treatment on medical lines should be carried out. This might in some cases result in the healing of the ulcer and the cure of the patient, but it would at any rate place the patient in a more suitable condition for undergoing operation subsequently should this be necessary. In a case in which diagnosis had been established, if the history showed only a duration of a few weeks, there was strong reason for the postponement of operative measures. His recommendations were complete rest in bed and regular feeding every two hours with 6 oz. of citrated milk, to which was added 20 grains of sodium bicarbonate. Over-citration of the milk was to be avoided, since it predisposed to haemorrhage. The first important part of the treatment was the removal of the source of infection from the mouth. A careful examination of the teeth should be made. In his experience oral sepsis was the most important cause of gastric ulcer. Sir William Willcox continued:

In my experience oral sepsis is the most important cause of gastric ulcer, and in cases where the gums and teeth are to external appearances healthy there is frequently found by a careful x-ray examination evidence of apical dental infection in the shape of apical dental granulomata or even abscesses. In all cases an x-ray examination of the teeth should be made, and teeth showing evidence of being sources of infection should be removed. It is well for such teeth to be submitted to a bacteriological examination, care being taken to prevent external contamination as far as possible. Almost always in these teeth evidence is obtained of the presence of streptococci other than those which are the inhabitants of the healthy mouth. Since oral sepsis as a causative factor in gastric ulcer is generally accompanied by a like infection of the intestinal tract it is advisable for daily Plombières colon irrigations to be carried out for a few days and a bacteriological examination made of the intestinal washings. In many cases an abnormal preponderance of pathogenic streptococci will be found. A combined vaccine of the streptococci from the mouth and intestines may with advantage be made and reserved for use if required. When the mouth has been set in order and the colon irrigations carried out for a few days treatment on the following lines is advisable.

Diet on the lines laid down by Lenhartz has been found most satisfactory, and coupled with this a mixture containing bismuth carbonate 20 grains, magnesium carbonate 10 grains, with 40 grains of sodium bicarbonate, given an hour after food.

To the mixture glycerin of carbolic acid 5 to 10 minims may be added with advantage for its antiseptic properties, and in cases of hypersecretion tincture of belladonna in 5-minim doses should be added. Large doses of alkalis must be given to be effective, and they should be repeated at four-hourly intervals.

In this connexion may be mentioned a case of pyloric ulcer in a medical man whom I saw twelve years ago. He had had three severe attacks of haematemesis and melaena at intervals of a few months from a pyloric ulcer, and in consequence of this I advised operation, but in the interim he was to take a mixture of bismuth carbonate and sodium bicarbonate in large doses three times a day. The patient was very averse to operation, and said to himself, "If the medicine is really effective, surely it should be taken at night as well as by day," so he took the medicine every four hours day and night for three weeks. He made a complete recovery without operation, and has been well ever since.

In my experience medicinal treatment on the lines laid down above usually results in apparent cure in early cases.

Recurrent Cases.—It is very common to meet with cases where several attacks of gastric symptoms have occurred, each lasting several weeks or months. In such cases a course of treatment on the lines laid down should be carried out, but if when the patient has reached the full dietary on Lenhartz lines symptoms should still recur surgical treatment is advisable.

Haemorrhage.—In cases of gastric ulcer where the diagnosis has been established (I am not referring to cases of gastrostasis or haematemesis from other causes than gastric ulcer)

the usual remedies for the arrest of haemorrhage should be given including serum injections. It is advisable, in my experience, to withhold all food by the mouth except occasional teaspoonful sips of hot water or a little ice. Normal saline should be given per rectum every four to six hours, as much as can be retained, to which may be added 2 per cent. of glucose. Five days after the haemorrhage has ceased Lenhartz diet should be given. It is extremely rare in my experience for a patient to die from haemorrhage from gastric ulcer, and I do not favour surgical treatment in the acute stage of this condition. When, in spite of treatment, the haemorrhage recurs, operation may be necessary.

In one case recently under my care the patient had four recurrent attacks of haematemesis at intervals of about six days. Since a fatal result seemed probable without surgical treatment, my colleague, Mr. Maynard Smith, operated upon the patient, who was given immediately before the operation a blood transfusion. This procedure was most satisfactory, and the patient made a good recovery, putting on 2 st. in weight after the operation.

Gastric lavage, with solution of sodium bicarbonate 1 drachm to the pint, has been found useful in cases of pyloric ulcer associated with spasm of the pylorus, and this followed by medicinal treatment may be successful.

Occurrence of growth in gastric ulcer is so rare, in my experience, that the possibility of its occurrence should not deter one from carrying out careful treatment on medicinal lines in cases of gastric ulcer. The very interesting observation of Dr. Spilsbury in the previous discussion supports this line of action. In cases of hour-glass contractions of the stomach symptoms persist usually in spite of medical treatment, and surgical treatment is necessary. In cases of pyloric obstruction, which does not disappear under medical treatment, surgical treatment is necessary and gives brilliant results. In cases with recurrent attacks with haemorrhage surgical treatment is indicated. In cases of chronic ulcer in which medical treatment fails to give permanent relief surgical treatment is advisable. It need hardly be said that immediate surgical treatment is imperative where signs of perforation are present. The physicians will look forward with interest to the methods of surgical treatment advocated by their surgical colleagues. It may be added that after surgical treatment in some cases a recurrence of symptoms may occur after, perhaps, a long period. In such cases careful search should be made for any possible source of toxic infection. It will often be found in the mouth or intestine, and if removed an amelioration or cessation of the recurring symptoms is to be expected.

Dr. A. B. SOLTAN said that all speakers had suggested an infective origin of gastric ulcer, or at any rate the possibility that it need not originate from a local cause in the stomach, and this, he thought, was an extremely important point to remember and to inculcate in the teaching of medicine. It was generally agreed that repeated haemorrhage threatening life required surgery, and that probably cases constantly relapsing were subjects for operation. The acute peptic ulcer was essentially a medical problem, and one which should invariably be cured and remain cured by treatment on medical lines. Whether or not chronic ulcer was the same type of lesion was very difficult to determine. Personally he had not often found, on examining cases with chronic ulcer which were in the fourth decade of life, any history of ulcer during the previous decades. The so-called chronic ulcer was the difficult part of the problem. At what point should medical treatment be despaired of? How many relapses should there be before the physician confessed that the case was beyond him? As a partial answer one would suggest that it depended upon the economic condition of the patient, because undoubtedly one could, if not cure, at any rate render more comfortable those who were in easy circumstances and who were not exposed to the daily toil of wage-earning. Such cases needed at least twelve months of careful watching, dieting, and treating if a satisfactory recovery was to be made. He pleaded for team work in the profession in order to arrive at a more satisfactory position with regard to gastric ulcer. While the literature and the statistics suggested considerable success, he knew in practice that there were a lamentable number of cases following operation which were in no way bettered, but continued to have pain, vomiting, and wasting, largely because efficient after-treatment had not been maintained, and also because the psychological side of the treatment had been neglected.

Mr. A. J. WALTON spoke chiefly of perforated ulcers. "That an operation should be undertaken in so grave a complication was beyond question. The only doubt was whether gastric perforation could occur with an acute ulceration. A careful investigation in the post-mortem department had shown 79 cases of perforation, 78 of which were chronic ulcer, and

of the other no note was made as to whether it was acute or chronic. He believed that an ulcer which perforated was always chronic; therefore suture alone was insufficient and gastro-enterostomy should be done. His own figures showed 32 gastric perforations with 13 deaths, and 19 duodenal perforations with 5 deaths. The mortality of 35.2 per cent. was high, but he had never refused operation even in the most severe cases. Pyloric and duodenal ulcers were satisfactorily treated by posterior gastro-enterostomy. There were two possible objections—one that carcinoma might arise at the seat of the ulcer and the other that the operation might be followed by gastro-jejunal ulceration. A careful attention to the clinical history would often reveal the presence of very early carcinoma, and if the history left any doubt as to the nature of the lesion, partial gastrectomy should always be performed. The danger of gastro-jejunal ulcer appearing was real; the frequency about 2 per cent. He did not believe that occlusion of the pylorus increased the frequency. The doubt was whether the danger of onset of gastro-jejunal ulcer was sufficient to demand partial gastrectomy as a routine. The mortality of this operation was bound to be high, and in this respect would outweigh the risk of gastro-jejunal ulcer. The speaker also discussed ulcers on the lesser curvature. Gastro-enterostomy, while it would not always cure a lesser curvature ulcer, often led to considerable improvement; with a very large ulcer it was his custom not to perform a jejunostomy, but a gastro-enterostomy with occlusion of the pylorus; in several cases there were recurrences after a year or so, but a second operation then would reveal an ulcer so decreased in size that excision was easily possible. If gastro-enterostomy was unsatisfactory, operation would have to consist either of gastrectomy or of local treatment, such as excision or cauterization, which must be combined with gastro-enterostomy to prevent recurrence.

Mr. H. W. CARSON said that his surgical methods had undergone a certain transition. He began by doing gastro-enterostomy in practically all cases of gastric ulcer, but the proportion of perfect cures was not high enough to satisfy him. About four years ago he adopted some form of partial gastrectomy, at first sleeve resection in selected cases, and was well satisfied with the results, but the scope of this treatment was limited to ulcers in the lesser curvature and the simpler forms of hour-glass. His next step was to do Billroth II for lesser curvature ulcers, and, as a natural consequence, the Polyn operation modified as recommended by Sir Berkeley Mouillhan. As a result, he now restricted gastro-enterostomy entirely to a proportion of prepyloric and pyloric ulcers, and instead of some 60 per cent. of perfect results he had 83 per cent. (His figures were very accurately determined because it was his custom at stated intervals to review the result of his gastric operations by getting in touch with his patients, and his last period of review embraced 118 cases of gastric or duodenal ulcer.) The really difficult ulcer was the chronic lesser curvature ulcer which had progressed to the saddle-ulcer stage or had become adherent to the pancreas. For saddle and adherent ulcers he adopted the Lardenois-Pauchet approach through the posterior attachment of the great omentum to the transverse colon, opening the lesser sac and stripping the colon away at the same time; this seemed to give the clearest view of the nodule and make separation fairly easy, safeguarding also the middle colic vessels. In perforation he was in favour of the least possible operation: he did not excise the ulcer, nor did he perform a gastro-enterostomy, nor wash out the peritoneal cavity. He was content to sew up the perforation, infold it, and drain the pelvis through the suprapubic wound, using no drain in the upper abdomen. There was no doubt that if cancer was excluded gastric operations were attended by very low mortality. In 54 consecutive operations for gastric ulcer, in 29 of which some form of partial gastrectomy was done, he had had only one death, and that in a case almost hopeless from the first.

Mr. J. E. ADAMS said that the reason why surgeons favoured excision was that, whatever might have been said by Dr. Spillbury in the previous discussion, there was in the back of their minds the thought that in excising cases of chronic ulcer they were preventing the patient from getting carcinoma of the stomach. He had looked up his hospital records of cases of carcinoma of the stomach in which a gastro-enterostomy had previously been done, and he found one, or sometimes two, of these cases in a year out of between thirty and forty cases of carcinoma. That was not a large proportion, but he had come to the conclusion that gastro-

enterostomy was a very poor preventive of carcinoma if the conditions were such as to favour carcinoma eventuating from chronic ulcer.

Mr. GORDON TAYLOR favoured partial gastrectomy, because he had found it give extremely good results. He followed this procedure in ulcers on the lesser curvature and near the pylorus, and particularly in ulcers which had given rise to severe hæmorrhage, and reserved gastro-enterostomy for the smaller ulcers, with or without excision. Out of 42 partial gastrectomies, the mortality amounted to 7 per cent.—too high, but still, having regard to the nature of the cases, not unsatisfactory.

Dr. E. P. FOULTON raised the question why some ulcers became chronic. There were certain mechanical conditions about which little was known, but which very often could be relieved by gastro-enterostomy; it might, for example, be retention of wind, coupled with the movements of the stomach, which kept the ulcer from healing. With regard to medical treatment, the main point was rest in bed, and of course very light diet, with frequent meals and the administration of alkalis. He believed that the important part of alkaline treatment was the liberation of CO_2 , affecting the distension of the stomach and altering the motility.

Dr. NEWTON PITT, in summing up the discussion, remarked that there was more to be said for medical treatment now than was the case some years ago. As yet it was not possible to say what was the cause of the ulcer nor the factors which made it persist (for the symptoms did not run co-ordinately with the keeping up of the hyperacidity). The majority of ulcers, however, did respond to medical treatment; if they did not so respond within a reasonable time there must be some definite cause, such as adhesions or spasm of the pylorus. In cases whose symptoms were not cleared up within a few weeks no medical treatment was going to do any good at all. Such cases must have operative treatment, either by gastro-enterostomy or gastrectomy. A great deal had still to be learned with regard to the after-results of gastro-enterostomy. On the South Coast, he believed, some practitioners saw quite a number of cases in which gastro-enterostomy had been done, with unsatisfactory results and persistence of symptoms. As time went on, the tendency would be for hypertonic stomachs to be treated by gastrectomy rather than by gastro-enterostomy.

ENLARGED PROSTATE.

THE fifth meeting of the Ulster Medical Society was held in the Medical Institute, Belfast, on January 26th, with the President, Dr. ROBERT HALL, in the chair.

Mr. A. FULLERTON read a paper entitled "Hints on the diagnosis and treatment of cases of enlarged prostate." The paper was illustrated by a number of very fine lantern slides. The lecturer pointed out that enlarged prostate was by no means a condition peculiar to old age. He had had a case where the symptoms began at 36; in another patient, aged 45, he had removed the prostate for non-malignant enlargement. The nature of the obstruction varied, and the types were described. The symptoms were classical and well known. Many had an enlarged prostate, but did not suffer from it; and on the other hand, the symptoms might be due to other causes—calculi, papilloma, etc.; the cystoscope might be dangerous, and its use demanded the greatest caution; the catheter and x-ray examination were of great service in making a diagnosis. With regard to treatment, the patient must be instructed in the necessity of immediately satisfying the desire to micturate; he must relax and not press, and, of course, avoid chill, prolonged motor drives, alcohol, etc. He had used the x-rays, and found improvement in some, not in others. He had not tried massage. He emphasized the warning not to empty a very distended bladder at once; it was remarkable how such distensions occurred without pain; sudden emptying might cause sudden congestion of the urinary tract from relief of pressure, and so suppression and death; a clip on an india-rubber catheter left in the bladder could be used and avoid the danger by letting away a little urine at a time; for the same reason operation should not be undertaken during retention. His plan was to tie in a catheter, irrigate daily for sepsis, and operate at the favourable moment; the treatment of hæmorrhage and cystitis was on the same lines.

Mr. Fullerton then gave his experience of renal inefficiency, and referred to Dr. W. W. D. Thomson for the methods of testing the functioning of the kidney. He said he had had

the greatest improvement in doubtful cases, due to rest, attention to diet, and either tying in a catheter or doing a preliminary cystotomy; the prostate was removed ten days later. He referred to the urethral and perineal operations and their success in the hands of the originators. He always carefully explored the bladder through the suprapubic wound.

Dr. W. W. D. THOMSON said he relied most on the phenol red colour test and on the estimation of the blood urea; he divided these prostatic cases into three groups. The first contained those who had 30 per cent. of the phenol red and below 0.7 per litre of blood urea; these admitted operation any time. The second contained those who had 20 per cent. of phenol red and from 1 to 7 urea per litre of blood; these were borderland cases and required rest, free evacuation of urine by retained catheter. The third group were still less satisfactory and were mostly inoperable. He thought the question of anaesthetics was very important, owing to the large number of these patients who had acidosis.

Mr. S. T. IRWIN rather objected to tying in a catheter; he had favoured lately the preliminary cystotomy.

Dr. MORRISON referred to the huge distension of bladders without pain and to the difficulty of diagnosis between simple and malignant enlargement of the prostate.

Mr. CRYMME raised the question of introducing the hand into the bladder.

Mr. FOLLERTON, in replying, said he favoured gas and oxygen as an anaesthetic. Spinal anaesthesia had not been satisfactory; the first stage, of course, was done under a local anaesthetic; 15 per cent. of cases turned out to be malignant; the most difficult was the small fibrous prostate. He enlarged on the advisability, where the patient could stand it, of the Thomson Walker operation, making the prostatic and cystic cavity into one.

HYPERTHYROIDISM IN PREGNANCY.

The annual meeting of the North of England Obstetrical and Gynaecological Society was held at Manchester on January 20th, when Mr. Harold Clifford, Manchester, was elected president for the ensuing year. The retiring president, Mr. CARLTON ODERFIELD, delivered a valedictory address on the treatment of pernicious vomiting of pregnancy. He said that he had met with 29 cases during the last fifteen years; there had been no deaths, and he had emptied the uterus only in one instance. His treatment consisted in removal of the patient to a hospital or nursing home, prescribing ordinary diet, and to have any bowl in which to vomit.

Mr. (Liverpool) read a paper on hyperthyroidism during pregnancy. The thyroid and parathyroids, he said, formed one glandular unit intimately concerned with the growth of cells, the full development of the normal functions of the sexual organs, and the regulation of calcium metabolism. Special activity was seen at puberty, during menstruation, and especially during pregnancy, when the extraordinary foetal demands for calcium led to a physiological hyperthyroidism.

Three clinical groups were described: (1) Physiological hyperthyroidism, characterized by symptomless enlargement of the thyroid gland, and occurring in 50 per cent. of pregnant women. (2) Graves's disease, a condition not due to simple thyroid excess, but the result of to the whole endocrine system and therefore 's disease was rarely found associated with pregnancy. (3) Minor degrees of hyperthyroidism were relatively common, and the speaker described fifteen cases in which the symptoms of hyperthyroidism were combined with others suggestive of tetany.

Calcium depletion, the result of prolonged lactation, rapid child-bearing, and insufficient nourishment, appeared to be an important etiological factor, and called in such cases for the exhibition of calcium salts. In addition, parathyroid had been given in order to meet a possible deficiency, suggested by the clinical resemblance to tetany, and also because this gland appeared to have a definite action in fixing calcium in the tissues or preventing undue elimination by the blood. His results had been encouraging, and in many cases all troublesome symptoms had disappeared.

At a meeting of the Newcastle-upon-Tyne and Northern Counties Medical Society, held on February 2nd in the library of the Royal Victoria Infirmary, an address was delivered by Dr. S. A. KINNIE WILSON on "Common nervous symptoms and their diagnostic significance." The lecture was illustrated by lantern slides, and will be published in full in the *Journal of the Society*.

Rebels:

THE AUTONOMIC NERVOUS SYSTEM.

PROFESSOR J. N. LANGLEY of Cambridge has begun the publication of a book on *The Autonomic Nervous System*.¹ The leading part in the elucidation of the functions of this system has been taken and is being taken by British physiologists, and Professor Langley, would he put his modesty aside for a moment, might well say *quorum pars magna fui et, we will add, sum*. The book, it may be assumed, will, when complete, be a full presentation of the present state of knowledge, and already we find physicians and surgeons applying that which has been acquired to the diagnosis and treatment of disease.

In the section now published (Part I) Professor Langley begins by discussing the varied nomenclature of the system of nerves to which, in 1898, he applied the name autonomic, having in mind a local autonomy. It is admitted that the adjective autonomic may suggest a much greater degree of independence of the central nervous system than in fact exists, except perhaps in the part of the system situated in the walls of the alimentary canal, but it is considered to be more important that new words should be used for new ideas than that the words should be accurately descriptive. The superiority of the title autonomic over the terms already employed, such as vegetative, involuntary, and ganglionic, is vindicated, and the autonomic nervous system is defined as consisting of the nerve cells and nerve fibres by means of which efferent impulses pass to tissues other than multi-nuclear striated muscle.

Professor Langley supplies a table in which the peripheral nerves, with the exclusion of the olfactory, optic, and auditory, are classified into the somatic, afferent (dromic and antidromic action) and efferent to striated muscle; the autonomic system is divided into the sympathetic (thoracico-lumbar), the enteric (plexuses of Auerbach and Meissner), and the parasympathetic, including the bulbo-sacral and the tectal divisions supplying special parts—for example, in the case of the tectal division, the sphincter iridis and the ciliary muscle. The sympathetic, on the other hand, is distributed to the whole of the body. But it does not follow that either system of nerves has an appreciable effect on all the structures in the region to which it runs; thus, although both the sympathetic and the parasympathetic nerves run to the eye, it is an open question whether any part of the eye is innervated by both nerves. In the chapter dealing with the nerve fibres of the autonomic system W. H. Gaskell's epoch-making work, dating from 1886, is critically considered.

In the section devoted to the specific action of drugs on the sympathetic and parasympathetic systems it is shown that, although adrenaline and some related substances produce effects nearly always like those caused by stimulating sympathetic nerves, and pilocarpine and muscarine produce effects usually resembling those produced by stimulating parasympathetic nerves, yet the correspondence between the action of drugs and nerve stimulation is not absolutely exact. The problem of the cause of the correlation between adrenaline and sympathetic nerve action on the one hand, and that of pilocarpine and parasympathetic nerve action on the other is fully discussed.

The last chapter deals with the tissues innervated by the autonomic nervous system; cardiac muscle, nearly all unstriated muscle, most glands, and some pigment cells have been proved to be affected by efferent autonomic nerves; the details of innervation are for the most part reserved for consideration under the separate nervous systems, but the question whether the cutaneous pigment cells, capillaries, and striated muscles are innervated by any part of the autonomic nervous system is exhaustively discussed.

In conclusion, it may be said that this volume sets forth a closely reasoned argument based on many years of research and a complete knowledge of the labours of others on the subject.

SURGICAL DIAGNOSIS.

In reviewing books on clinical diagnosis for English students there is necessarily some reserve. Our tradition has been, until lately, to teach students clinical surgery and medicine over the bed and not from books. It is to be hoped that the

¹ *The Autonomic Nervous System*. Part I. By J. N. Langley Sc.D., LL.D., Hon. M.D., F.R.S., Professor of Physiology in the University of Cambridge. Cambridge: W. Heffer and Sons, Ltd. 1921. (Demy 8vo, pp. 80; 1 figure. 5s. net.)

system currently fashionable will not lead to the sacrifice of that invaluable practice, with the necessity for lavishly illustrated books on diagnosis to which in Bernie the issue of a seventh edition of DE QUERVAIN'S already well-known work is witness. That a third edition in English should be called for is the best evidence that here too—and in America—such books are needed. It may be that "practitioners" do find help from an up-to-date textbook in supplying what they can no longer see daily, as the student does, in hospital beds. It is well, therefore, that so excellent a book, so thoroughly illustrated, so competently translated as Professor de Quervain's *Clinical Surgical Diagnosis for Students and Practitioners* should be at their command. The author has always pursued the plan—in principle universal, but in this country recently associated with the name of Mackenzie—of starting from the symptoms of which the patient complains, and of keeping them in view whilst narrowing down the problem by suitable questions until positive observations permit diagnosis.

It is perhaps impossible to write a book of general guidance for problems thus essentially individual, but the author has attacked his task in the spirit of one who habitually assumes this attitude to his patients, and the result is a successful manual.

NARROW JAWS AND ARCHED PALATES.

Deformities of the jaws and palate are extremely common among members of the civilized European races; the narrow pointed dental arch, the Gothic highly-arched palate, and the underdeveloped lower jaw, appear to be so particularly associated with adenoids that it is natural to suppose that the nasal obstruction is a direct cause of the deformity. It is easy to build up a theory of how the alteration of stresses set up by an habitually open mouth produces the alteration of shape, of how, when the mouth is closed, the tongue exerts a suction on the palate and an outward pressure on the sides of the dental arch, and of how, when the mouth hangs open, the cheeks press inwards on the molar teeth. It is, too, a simple matter to assume that the highly arched palate allows insufficient room for the growth of the nasal septum, which accordingly becomes bent.

In a monumental work on growth and deformity of the jaws and nasal septum Dr. GUSTAV FRANK² has published the results of a most thorough and elaborate series of measurements of jaws and palate, and his observations go far to destroy these fascinating theories. For instance, he finds that highly arched palates are very little narrower than normal ones; at various ages the height is increased by 3 to 3.9 mm., but the width only diminished by 0.4 to 1.1 mm.; he concludes, therefore, that this deformity cannot be caused by lateral pressure on the jaws. As to deviations of the nasal septum, Franke finds that these are often visible even in foetal life; he believes that the majority are not due to transmissibility, because in his examination of a large number of skulls he has often found healed fractures without deformity, and because he has found severe deflections without trace of injury; and he points out that fractures of the cartilage can only unite by fibrous tissue, and are therefore permanently recognizable. Also, although septal deviations are common in skulls with narrow jaws and high palates, he gives reasons for believing that they do not stand in a direct causal relationship; in his opinion deformities of the septum are caused by lack of space for its growth due to a general underdevelopment of the upper jaw and flatness, or "pugging," of the face. All these deformities are the result of a lack of stimulus to growth which results from insufficient use of the jaws in mastication, because the civilized races eat only soft food, and the reason that these deformities are especially related to mouth-breathing is simply that the subjects of nasal obstruction chew their food even less than the normal civilized man.

Dr. Franke has perhaps paid too little attention to a possible racial tendency to "pugging"; but this is a factor which cannot be measured, unless the entire race would revert to the diet of our primitive ancestors, so that it might

be seen whether the new generation would arise free from these deformities. Dr. Franke's work is suggestive and painstaking; almost too painstaking indeed, for his main arguments are overlaid by a mass of detail and of references to other workers.

ANATOMICAL NEUROLOGY.

A THOROUGHLY satisfactory work on the *Anatomy of the Nervous System*¹ would be a book on the one hand accurate enough in detail to satisfy the most exacting neurologist, and on the other sufficiently clear and simple "to be understood of the people." Such a book has been written by Professor RANSON of Chicago. This work, we feel sure, will be accorded a warm welcome by both student and teacher. The author demonstrates the old truth that he who is most master of his subject can, if he avoids elliptical argument and allusion, write of difficult things in the simplest manner.

The author's conception of the teaching of neurological anatomy is that, in order to make the subject sufficiently alive, it is essential that the study of structure should walk hand in hand with the study of function. So well have the two been interwoven here that the book might well have been given a physiological title. The study of the tracts of the cord, of the structure of the mid- and hind-brains, is thus made a living thing. Moreover, where knowledge is as yet imperfect, the facts are clearly and judiciously stated. The account of the cranial nerves is singularly well done, a provision of simple diagrams making the crooked ways of the nuclei of origin and terminations clear and understandable. The most difficult section of all, the anatomy of the cerebellum in relation to function, is something of a test chapter. The work of Elliot Smith, Ingrar, and Bolk is related, the author maintaining a neutral attitude towards the question of localization of function within the cerebellum. The chapter on the sympathetic nervous system is too short, and might be improved by more reference to pathological physiology. Presumably the question of the liaison between this system and the endocrine glands was deemed too purely physiological for inclusion.

The book is admirably produced, and the simple drawings are most commendable. There is a good index.

BOWEL DISEASES IN THE TROPICS.

SIR LEONARD ROGERS'S *Bowel Diseases in the Tropics*³ represents two of his previous works, revised and rewritten—namely, that on cholera and its treatment and that on dysenteries. The new volume is a companion to his well known work on *Fevers in the Tropics*, and bears the same impress of authority and wide experience. The first two hundred pages are given to cholera, and contain amply documented accounts of its history, epidemiology, etiology, morbid anatomy, clinical aspects, and treatment. The author's own methods of treatment, evolved in the course of treating over two thousand carefully observed and recorded cases during twelve years' work at Calcutta, are fully detailed. They consist as is well known, primarily in the use of hypertonie saline injections at the critical moments, and have resulted in a reduction of the death rate to one-third of what it was before their employment. He is convinced that opium in all its forms is injurious in cholera, once the typical colourless motions have set in.

The second part of the volume deals with dysenteries and liver abscess on similarly broad lines and with equal fullness; in particular the employment of emetine in amoebic dysentery and the often associated amoebic hepatitis or liver abscess, first advocated by the author in 1912, is set out in all detail.

The book gives a singularly complete account of the diseases with which it deals, is clearly written, and abounding in the practical hints and directions that are so important to the practitioner who has to treat patients. The illustrations are excellent and the volume is adequately indexed. It should be in the hands of all medical men resident abroad, and be studied by all interested in tropical diseases.

London: H. Frowde, and Hodder and Stoughton, 1921. (Demy 8vo, pp. xvi+775; 15 plates, 50 tables, 3 diagrams, 2 charts. 35s. net.)

ORGANIC CHEMISTRY.

MR. HAMMICK'S *Introduction to Organic Chemistry*⁶ is a well-written little laboratory book for use by junior students of chemistry who already have a knowledge of the simpler methods of organic laboratory practice. It is not designed to meet the claims of any particular examination syllabus, but its fourteen chapters and round gross of experiments seem enough to furnish the student with a sound working knowledge of organic chemical structure, notation, and technique. The word "affinas" on page 116 should read "affinis." The book contains a great deal of information useful to the student of chemistry, and may be recommended to him.

The second edition of Professor STEEL'S *Laboratory Manual of Organic Chemistry for Medical Students*⁷ is an unusually good type of practical handbook, for the author has kept in mind the particular variety of organic chemistry that is likely to be of service to medical students in the later stages of their curriculum. He has added to this edition an excellent chapter of experiments in colloid chemistry that should be of great help in clarifying the ideas of the student; for colloid chemistry, by this time a well-explored kingdom, is a subject with which he is usually but little acquainted. The text in this volume is confined to the left-hand pages; the right-hand pages are left blank for notes and records of experiments.

MR. MACBETH'S short handbook of *Organic Chemistry*⁸ is based on his course of lectures to his pupils, and is designed to fill the wants of medical, pharmaceutical, and intermediate science students. It is clearly written and practical in its treatment, and examination questions are set at the ends of the chapters. The book may be recommended to those for whom it is designed.

THERAPEUTIC NOVELTIES.

MERCK'S annual reports,⁹ which have appeared regularly since 1887, give short abstracts of the experimental and clinical papers, published during the year under review, which deal with the more important therapeutic novelties. These reports are a boon to anyone who wishes to investigate the action of a new drug, for they provide an up-to-date account of the work which has been done upon the subject; information can be obtained from them in a minute to find which, without their help, would require hours of tedious work.

The present issue deals with two years: about 500 drugs are reported upon, and 1,300 references are given to articles in 200 different journals published in 17 different countries in about 10 different languages. These figures indicate the industry and care with which the medical literature of the world has been searched. They are, however, rather appalling, when we reflect that they only represent a fraction of the output of therapeutic literature in two years. A special article is devoted to the therapeutic use of the benzyl derivatives (80 references); these substances were introduced by Maelit, who is credited with having written twenty-one papers on them in four years; benzyl acetate, the best known of these substances, is recommended for all forms of spasmodic contraction of plain muscle. Silver-salvarsan (about 60 references), and protein therapy (about 50 references), are two other subjects of particular importance which are dealt with very fully.

The report consists of highly condensed summaries of an enormous mass of literature, and it is naturally impossible to give any general account of the book, except to say that it contains an account of all the well-known therapeutic novelties, and that the references appear to be very complete. The exact value of the bulk of the literature so carefully collected in these reports appears, however, to be a little doubtful, for in the case of every drug every observer

appears to have got uniformly successful results. The various remedies reported upon cover practically every known disease, and they all appear to be infallible remedies, yet vital statistics assure us that people continue to die from causes other than old age.

NOTES ON BOOKS.

THE eighth edition of Professor HARE'S *Symptoms in the Diagnosis of Disease*¹⁰ is an excellent book for the medical student who wishes to learn how to employ his eyes, ears, and hands to the best advantage in examining patients. The author omits laboratory methods, and has endeavoured to write a book that will enable the recognition of symptoms and physical signs to lead to a diagnosis. The first six chapters are given to the face, arms, legs, hemiplegia, speech, and the skin; then follow chapters on the mouth and tongue, abdomen, bowels, thorax, pulse, urine, and eye. The rest of the book is given to various important symptoms. The text is clear and concise, and is helped out by a number of illustrations; in many ways old-fashioned, the book yet contains a great deal of sound practical teaching.

Professor BIRK'S guide to the diseases of children¹¹ is a companion volume to his book on the diseases of infants, and is addressed to students and practitioners of medicine. The author describes spasmodic asthma as rare in children, does not mention its connexion with food poisoning, and remarks that it will disappear as the child grows older. Other examples of the author's failure to do justice to his subject might be quoted; the book is not one that we feel able to recommend.

Golden Rules for Dental Mechanics,¹² a small volume prepared by Mr. HAROLD OSBORN, a member of the Society of Chemical Industry, is an excellent little book, containing many valuable and accurate notes for dental mechanics; it will be of interest also to dental students. We have noted some inconsistencies: on the first page the author gives in ounces the proportion of plaster-of-Paris and water that should be used in order to obtain the greatest strength in a plaster cast, but on page 20 he modifies this by saying that the plaster should be mixed as stiff as it can properly be worked. He would have done better to adhere to his original statement. In another place he says that sticky wax should always be removed with a spatula, and that heat or boiling water should not be used. We doubt whether it is always possible to remove wax with a spatula, and know no reason why heat should not be used.

A new edition has appeared of Dr. ERICH WOSSIDLO'S *Kystoskopischer Atlas*,¹³ first published about a year ago. Advantage has been taken of the publication of this new edition to make certain slight additions. The most important of these is the inclusion of some new coloured plates which have thereby been increased in number from thirty-four to forty-two. They illustrate not so much new types of disease as variations of bladder conditions that have already been represented. Alterations have also been made in the text, and new diagrams added to illustrate the section on the optics of cystoscopy.

MR. JOBLING'S *Catalysis and its Industrial Applications*¹⁴ is a well-written little book. Catalysis is a process which has since in a great many industrial processes, and of late years their modes of action have been studied with no less profit than care. The volume may be recommended to all who are interested in the scientific side of industrial manufacture.

Dr. JOLTRAIN'S little book on plague¹⁵ gives an account of the epidemiology of the disease, its connexion with the rat, and of its symptoms, treatment, and prophylaxis. It is written for the use of medical practitioners, and contains all that is necessary in an elementary handbook.

¹⁰ *Symptoms in the Diagnosis of Disease*. By H. A. Hare, M.D., B.Sc. Eighth edition, thoroughly revised. London: H. Kimpton. (Roy. 8vo, pp. 574; 195 figures. 35s. net.)

⁸ *Organic Chemistry for Medical, Intermediate Science, and Pharmaceutical Students*. By A. Killen Macbeth, M.A., D.Sc., F.I.C., etc. London: Longmans, Green and Co. (Cr. 8vo, pp. 246. 6s. 6d. net.)

⁹ *E. Merck's Jahresberichte über Neuerungen auf den Gebieten der Pharmakotherapie und Pharmazie*. 1919-1920. XXXIII und XXXIV Jahrgang. E. Merck, Chemische Fabrik, Darmstadt. (Small 8vo, 365 pages. M. 18.)

A full account of the diagnosis and treatment of gastric and intestinal disorders is given in the third edition of Professor AARON'S *Diseases of the Digestive Organs*,¹⁶ a book that may be recommended to medical practitioners and specialists alike. The author writes in a practical spirit, and the book is not overloaded with scientific detail; the highly important subject of diet receives adequate treatment throughout, although it is described from the American rather than the European point of view. The volume is well printed and many of the illustrations and coloured plates are excellent.

Dr. McCaw's *Aids to the Diagnosis and Treatment of Diseases of Children*¹⁷ has reached a fifth edition. It is a well-written and fairly complete little volume that may be recommended to medical students in search of a small volume on the subject with which it deals.

*The Boy in Industry and Leisure*¹⁸ is the second volume in "The Social Service Library," and is intended primarily for the guidance of the social worker whose sphere of activity lies amongst those boys whose home influences, school life, circumstances or environment leave a gap that can be filled only by the social worker. The book describes how such boys can best be helped through a critical period of their development, and ends with an appendix containing much information as to the various schemes and agencies designed for their assistance. The author is particularly well fitted for the composition of such a volume as this, and it should be of great service to all interested in the welfare of the potential hooligan.

X RAYS, LIGHT, AND ELECTRICITY.

Dr. VOLTZ's volume on the physical and technical bases of x-ray measurement and dosage¹⁹ gives a general account of the subject, written for the information and instruction of medical men who make use of x-ray therapy. The treatment is theoretical rather than practical; the reader feels that somewhere within the bundle of hay there is a needle, or possibly more than one. For ourselves, we confess that we have not found it.

A pamphlet by the same author on dosage tables for x-ray therapy²⁰ is an exposition of a theory of quantitative x-ray dosage he has based on Seitz-Wintz's system of biological measurement. It is meant for the use of experts in x-ray therapy.

The seventh edition of BACH's book on treatment by the quartz lamp²¹ is divided into two parts. The first deals with the use of the apparatus described, the second gives an account of the indications for its employment in disease. The book is practical, and gives perhaps an optimistic account of what may be expected from light treatment. It will be consulted by specialists.

Dr. GASSUL's pamphlet on the significance of different rays for the diagnosis and treatment of tuberculosis²² gives a summary of the literature dealing with the use of Roentgen rays in tuberculosis, and the success with which sunlight, various forms of artificial light, radium and the like, have been employed in its treatment. Details of these forms of treatment are not given; the author calls for further research in this promising therapeutic field.

The sixth edition of COHN's outlines of electrodiagnosis and electrotherapy²³ is a book written for students and practitioners of medicine, and contains a full and practical account of the subjects with which it deals, adequately illustrated. It appears entirely suitable for the use of medical men resident in Germany.

MEDICINAL AND DIETETIC PREPARATIONS.

Salicylosol.

SALICYLOSOL is a solution of salicylic acid in a partly-oxygenated mineral oil. It is stated to contain 10 per cent. salicylic acid. Analysis in the laboratory showed 10.5 grams salicylic acid per 100 grams of solution. The oil has little taste when given by mouth. The manufacturers claim that it produces no nausea or other symptoms of gastric irritation such as follow the employment of sodium salicylate. This point has not been tested by us, but Hanzlik¹ tested the toxicity of various salicylate compounds on 400 patients and found that none possessed any advantage in this respect over sodium salicylate. Hanzlik found that toxic symptoms appeared on an average after a total of 200 grains (13 grams) of sodium salicylate had been given; this would correspond to about 4 oz. (115 c.cm.) of salicylosol.

Salicylosol is specially recommended for administration by the skin, and it is stated that when exhibited in this manner the physiological effects of the drug can be obtained without the undesirable effects which may attend administration of salicylates by the mouth. Impens² found that from 10 to 16 per cent. of the salicylic acid rubbed into the skin appeared in the urine. When 10 c.cm. of salicylosol (= 1 gram salicylic acid) was massaged into the skin we found that 0.137 gram appeared in the urine in 24 hours. Hanzlik³ found that a normal person excreted 40 per cent. of a dose of salicylate given by mouth in twenty-four hours. The absorption of salicylic acid from innaction is therefore only about one-third of the absorption of salicylic acid given by mouth.

From these data it follows that to produce a full therapeutic effect in a case of rheumatic fever by innaction of salicylosol it would be necessary to rub in about 12 oz. of salicylosol in forty-eight hours; it seems doubtful whether this is practicable. The therapeutic use of salicylosol appears therefore to have certain limitations which are not fully realized by the manufacturers. Salicylosol would seem, however, to be an excellent preparation for innaction, as it contains five times as much salicylic acid as the official salicylic ointment (B.P.), and when administered by innaction does not irritate the skin. The penetrative power of salicylosol compares very favourably with that of other salicylic preparations whose power of penetration has been recorded. The agents are Messrs. E. T. Pearson and Co., London Road, Mitcham, Surrey.

Iodinosol.

This is a non-irritant non-staining preparation of iodine in a base similar to that used in salicylosol. It is prepared in two strengths, 6 per cent. and 10 per cent. On analysis the 6 per cent. preparation was found to contain 6.5 gram iodine per 100 gram solution.

Iodinosol is an excellent preparation for innaction, as it is non-irritant, and when completely massaged into the skin produces no staining of the skin or of the clothes. When administered by the mouth it produces slightly irritant effects like other preparations containing free iodine.

The proprietors state that "a small quantity of iodinosol 6 per cent. may be rubbed into the region of the median vein, and fifteen to thirty minutes afterwards the presence of iodine in the urine can be shown by the usual test methods"; and that "in a word, it can be administered in every instance where potassium iodide, internally or externally, is indicated." We are not able to confirm these statements from our own observations. We found that thorough innaction of 10 c.cm. of iodinosol in man produced no excretion of iodine in the urine in the succeeding twenty-four hours. On the other hand, the administration of 0.01 gram KI by mouth or of 0.5 c.cm. iodinosol by mouth produced demonstrable quantities of iodine in the urine. These results agree with the observations of Weizel and Sollmann⁴ and of Kniepf⁵ who found that innaction of a large variety of iodine preparations produced no excretion of iodine in the urine.

A large number of workers have studied the absorption of iodine by the skin, and their results are curiously discrepant, but in general it appears that innaction of non-irritant iodine ointments produces little or no absorption of iodine in man.

¹ Hanzlik: *Journ. Amer. Med. Assoc.*, 1913, ix, p. 957.

² Impens: *Pfinger's Archiv.*, 1917, 125, p. 1.

³ Hanzlik: *Journ. Pharm. and Exp. Ther.*, 1916, 9, p. 217.

⁴ Weizel and Sollmann: *Journ. Pharm. and Exp. Ther.*, 1920, 15, p. 163.

⁵ Kniepf: *Therap. Zeitschrift.*, 1920, 34, p. 352.

although a considerable absorption may occur if strong iodine ointments are left in contact with the skin for long periods. It seems certain, however, that it is unsafe to rely upon sufficient iodine being absorbed by the skin to produce the general therapeutic effects of iodides.

The claim by the manufacturers that "Iodinosol is all absorbed promptly, thus ensuring prompt action and enabling the prescriber to regulate the dose of iodine to a decimal point of a grain," does not accord with our observations.

The agents are Messrs. E. T. Pearson and Co., London Road, Mitcham, Surrey.

A Simple Aspirator.

WITH reference to the description by Dr. H. O. Gunewardene of an aspirator, published in the BRITISH MEDICAL JOURNAL, of January 21st, p. 109, Dr. J. Ashforth (Woodlands, near Doncaster), writes that he has used a similar combined aspirating syringe and trocar, supplied by Messrs. Pettie and Whitelaw, of Aberdeen and Dundee, which he considers possesses advantages over that mentioned by Dr. Gunewardene, since no rubber tubing is required, and the whole apparatus is of metal, easily detachable and convenient to sterilize.

MOTOR NOTES FOR MEDICAL MEN.

By H. MASSAC BUIST.

THE CARE OF THE CAR IN WINTER.

IN view of the large number of medical men who nowadays look after their cars, in whole or in part, and of the apparent change from an unprecedented spell of mild weather to the normal temperatures of winter, a few hints may be helpful. This is a season in which it behoves the owner to note the degree to which the motor-house is exposed. If it is facing due north, or east, and there is no warm compartment near it, because of the rapid changes of temperature likely to be experienced at this period, it is well to consider methods of artificial heating, or, alternatively, to make a practice of draining the water out of the radiator and cylinder jackets every night. The latter is a laborious course that occupies a considerable amount of time, particularly as the water has to be replenished in the morning. It is therefore in the nature of a last resort. Should the motor-house be sheltered from the coldest quarters, or built beneath a dwelling-place, such as a coachman's quarters, it will generally be unnecessary either to heat the garage artificially or to drain the water out of the cooler. In the case of the owner-driver I should always advise putting the car backwards into the garage in the summer months, then it stands conveniently for starting by hand. In any case, the minimum time is lost in getting away. By contrast, in cold weather the vehicle should be driven straight in and left so standing that it has to be backed out. Thus the vital parts will be farthest from the draught that can sweep in under the doors. But if there are no dwellings near the motor-house the question of artificial heating may require consideration.

A Simple Scheme for Occasional Heating.

Sometimes the simplest arrangements will suffice. It is not always necessary to install elaborate heating apparatus, particularly in face of the fact that such procedure may occasion trouble of the red-tape sort with the local authorities; also it may affect the fire insurance of the car. Some years ago, for two or three winters, I found the occasional use of an untippable paraffin lamp, costing 1s., sufficient for the purpose, even in a garage at a relatively high altitude in a very cold county. Once filled, one of these lamps will burn for the best part of twelve hours. If it is put on the ground it will introduce considerable extra warmth into the ordinary coachhouse, even when the door is ill constructed and admits a draught at ground level.

When, however, there is no course but to drain the water system, one point should be had in mind in particular: after all the liquid has come away from the taps at the base of the cylinder casting and the cooler, the engine should be run a few moments to enable the water circulating pump to expel any liquid in its neighbourhood. Many a case has occurred in which the owner has imagined he has expelled all the water from an engine system but has found subsequently that the mechanism has burst in the neighbourhood of the pump through the freezing of water that had accumulated and not been drained away. This can be obviated by the simple method of running the engine for a few moments after the water circulation system has apparently drained itself empty

by mere gravity. Usually the amount of petrol remaining in the pipe from the tank to the carburettor after the tap has been turned off will suffice to run the engine long enough for the purpose. Nor let anybody fear that running the engine in such circumstances in cold weather will cause difficulties. There is no such danger provided the lubrication system is adequately supplied with undiluted oil of the right grade. Whenever the water has been drained off, on preparing the car for use again hot filtered water should be used in preference to ordinary cold water. For one thing, that will vastly facilitate starting up the engine.

Aids to Starting.

Much remains to be done in the way of making cars easier to start in cold weather. When hand cranking was the rule more attention used to be given to this matter, despite the fact that, the further back we go, proportionately the easier engines were to start. On the one hand, in the pre-war period the quality of the fuel was better than the average available to-day, and, on the other, the compressions used for standardized car engines were lower, therefore it was not necessary to crank them as fast to get a start as is essential with post-war designs. Since the coming of the mechanical engine-starter, however, the need for easy starting has been largely overlooked, with the result that great burden is placed on the battery, and often much trouble results. By letting the mechanical engine starter turn the crankshaft for many seconds at a time without the mixture being fired, fuel may pass the pistons and, falling into the base-chamber, dilute the lubricating oil. Experiments recently carried out by an American manufacturer who had frequent troubles of this kind are reported to me privately to have shown that thirty seconds of cranking with a mechanical engine-starter, and with the throttle closed, resulted in half a pint of fuel flowing by the pistons into the crank case. Four cranking periods of this duration each day would thus result not only in wasting a quart of fuel, but a serious dilution of the lubricating oil, with all its grave risks. Such a case, however, must be regarded as altogether exceptional. But it is useful to have it in mind as an indication of a very prevalent source of trouble which may be experienced, in less degree, by any motorist. The better the construction the more important it is that no foreign matter should get mixed with the lubricant. A quarter of a pint of foreign liquid in the base-chamber of some engines would be sufficient to render the best lubricant quite incapable of doing its work.

When and How to Use Aviation Spirit by the Cupful.

A large percentage of cars are kept in unheated motor-houses, or are allowed to stand in front of doors for long spells during which the engine becomes cold. The higher the compression of the power plant the more rapidly the crankshaft has to be turned to have a chance of starting. Moreover, as there is every prospect that the fuels which will be supplied for service in cars will not tend to improve in quality, the importance of obtaining a quicker average start, as well as of controlling the cooling system whereby the engine temperature can be warmed up promptly to the degree required for correct operation, is worthy of study. While these problems largely concern the motor engineer and car builder, the medical man can do much to assist and protect himself in this connexion. For example, the use of radiator masks is now well understood in this country, particularly by doctors. Quilted masks are probably the best sort for medical men. It is not necessary, however, that the covering should extend over the whole of the bonnet; the important part is the radiator.

In regard to starting the engine from cold, a great many cars are equipped with carburettors a feature of which is that the undoing of two nuts, or even the sliding of a finger sideways, exposes the float chamber. All carburettors ought to have a drain tap at the base. All users ought to turn off the petrol tap when the vehicle is needed no longer. A good practice to ensure the best possible start in cold weather is to turn off the tap at the end of the day, and run the engine until the fuel in the carburettor is exhausted. On going to start the car up next day the fuel tap should still be left turned off. A tin of aviation spirit should be kept in stock. When needed a small bottle is filled with this spirit, and a little is poured into the float chamber, the top of which should then be put on promptly and the throttle left in the usual position for starting. By means of this best grade spirit it should be possible to get a very ready start by hand, or by means of the electric gear, in

CURRENT NOTES.

Annual Meeting, Glasgow, 1922.

IN the JOURNAL this week is published the third of a series of illustrated articles giving a descriptive and historical account of Glasgow and its institutions, for the benefit of members and their friends who propose to take part in the Annual Meeting next summer. A brief outline of the provisional programme was given in a Current Note last week. The Representative Meeting (which opens on July 21st) and the Annual General Meeting on July 25th will be held in the Bute Hall of the University of Glasgow; Council meetings will take place in the Randolph Hall of the University. The Scientific Sections will meet in the class-rooms of the University on Wednesday, Thursday and Friday, July 26th, 27th, and 28th, and the Pathological Museum will be arranged in the Anatomical Department. A religious service will be held in Glasgow Cathedral on July 25th, and Mass will be celebrated on July 27th in St. Andrew's Roman Catholic Cathedral. The programme of social events is taking shape under the general direction of Dr. George A. Allan, the Hon. Local General Secretary, and further details will be announced in due course. We mentioned last week that the golf competition for the Ulster Cup will be played over the course of the Glasgow Golf Club at Killermont on July 27th; we now hear that the President of the Golf Club, Professor J. Munro Kerr, M.D., and Mrs. Munro Kerr have offered to entertain 200 members to tea on that occasion.

A slip made in this column last week should be corrected. At the last meeting of the Association in Glasgow, in 1883, the address in surgery was delivered by Sir G. H. B. Macleod, and a special address on "Recent investigations in surgery" was delivered by William Macewen, M.D., now known throughout the world as Sir William Macewen, who will preside over the meeting of 1922.

A series of excellent articles on the history and work of the British Medical Association is now appearing in the *Glasgow Herald* from the pen of its well-informed and judicious medical correspondent. This writer acknowledges his debt to the outline of the medico-political history of the Association printed in the current *Annual Handbook*. It is an open secret that the author of this historical sketch is Mr. Russell Coombe, until lately Chairman of the Organization Committee.

Stewart Prize.

The Stewart Prize is awarded, either in recognition and encouragement of important work already done, or of researches instituted and promising good results, regarding the

origin and spread of epidemic disease, or, secondly, to a person (or persons) selected by the Council who is considered exceptionally qualified to undertake and conduct the investigation of such question or questions connected with the subject of epidemic disease as shall appear likely to yield important results. For some considerable time past it has been customary to award the Stewart Prize every two years, and in the ordinary course of events the award would be due during this year. Owing, however, to the reduced income of the fund, consequent upon the higher rate of income tax, it will be impossible to make the award this year. It is hoped that the balance standing at the credit of the fund will be sufficient to enable the prize to be awarded in 1923.

East African Medical Services.

A considerable volume of correspondence between the British Medical Association and the Colonial Office appeared in the SUPPLEMENT last year with reference to the status, pay, and prospects of officers of the Colonial Medical Services. As a result of prolonged negotiations, relations were established between the Association and the Colonial Office by means of which it was anticipated that the Association would in future be in a better position to safeguard medical interests in the Colonies and Protectorates. In the letter from the Association to the Colonial Office published in the SUPPLEMENT of June 4th, 1921, among the questions raised was that of the appointment of temporary medical officers in the East African Medical Services, a matter which had given rise to considerable dissatisfaction among the permanent members of those services. The discussion of this question has been continued with the Colonial Office, both by the Central Office and the Uganda Branch of the British Medical Association. In some of the Protectorates in Eastern Africa the shortage of medical staff had been deplorable, and in a letter addressed to the Colonial Office (SUPPLEMENT, June 4th, 1921, p. 203) the British Medical Association expressed its opinion that the only remedy was fair treatment and conditions of service for the medical staff, and pointed out that the unrest and dissatisfaction in this service was such as to act as a very effective check on recruiting. The Colonial Office evidently recognized that the shortage of medical officers was a matter which ought to be remedied, but the method by which it endeavored to remedy this shortage was to second R.A.M.C. officers as temporary medical officers in the East African Medical Services on full army pay and allowances (£762 per annum) plus £200 per annum. As the five senior medical officers in Uganda averaged twelve and a half years' service each, and their annual pay averaged just over £800 per annum, these appointments were looked upon as an injustice to them. Protests had already been made against the appointment of temporary medical officers at salaries of £700 per annum, with £200 bonus after completing thirty months' service, and these protests were renewed on

the appointment of officers seconded from the R.A.M.C. at an even higher rate of pay. The Uganda Branch of the British Medical Association was unanimously of opinion that suitable candidates for appointments on the permanent staff in the East African colonies were unlikely to come forward while the arrangement for seconding R.A.M.C. officers for temporary service on these terms remained in force, for it was obvious that no medical man of standing would apply for a post in East Africa at £600 per annum while the Colonial Office admitted in this way that it was worth £960. In Nyasaland two R.A.M.C. officers were appointed temporarily to fill vacancies on salaries of £814 and £981 respectively, and it was stated that others were to follow; senior medical officers on the permanent staff in the same area of from ten to fifteen years' service were receiving £700 to £800 per annum. As a result of these representations and the efforts of the British Medical Association, a letter has recently been addressed from the Colonial Office to the Medical Secretary of the Association (January 17th, 1922), stating:

"It has been explained to the Acting Governor that the position in regard to the supply of candidates for appointment to the Colonial Medical Services after the war continued to be difficult, and that in the early part of 1921 the War Office agreed to lend a strictly limited number of Royal Army Medical Corps regular officers for temporary service in East Africa for vacancies which it was desired to fill urgently; that three such officers were appointed, one to Uganda and two to Nyasaland; and that it is not intended that more of these officers should be appointed, as candidates for permanent appointment have recently become available in the ordinary way and difficulty similar to that previously experienced is not now anticipated."

It is a matter for congratulation that the Colonial Office does not intend to appoint any more R.A.M.C. officers, and it may fairly be claimed that the arguments which were put forward by the Uganda Branch of the British Medical Association, together with the representations made by the Central Office, convinced the Colonial Office of the undesirability of the course which had been adopted.

The Manchester Medical Officer of Health.

One of the chief problems which will confront the new medical officer of health for Manchester—whether he be appointed or not under the conditions which up to the present have been approved by the corporation of that city—will be the reorganization of its overlapping medical services. This question has apparently been shelved so far, but it is urgent, and the new medical officer of health will have to face it. According to the *Manchester Guardian* of February 3rd Manchester is served medically by two authorities, the Public Health Committee and the Education Committee; the Port Sanitary Authority is a third. The medical service of the Education Committee gets its grants not through the Board of Education but from the Ministry of Health, for that Ministry now controls the powers conferred by the Public Health Acts, the Lunacy Acts, the Mental Deficiency Acts, and the school medical departments both under the Health Act and the Education (Consolidation) Act, 1921. The London County Council, continues the *Manchester Guardian*, consolidated its health services in 1912, and now seeks wider powers; Liverpool did the same thing about 1908, Bradford in 1913, and Sheffield is considering consolidation. Liverpool has centralized public health, the school medical service, and the port sanitary authority, and it is chiefly with this last body that Manchester might find reorganization difficult, for the port sanitary authority of Manchester is a composite body to which many authorities pay tribute. Salford is closely concerned in the constitution of the latter, and its reorganization would inevitably raise thorny questions of joint municipal government between the city and the ancient borough.

The tackling of such a problem as this necessary reorganization will obviously require qualities in the new medical officer of health beyond those of a mere routine official. It remains, therefore, for the Corporation of Manchester to make up its mind whether it desires to have as its medical officer of health a man of the standing, mentality, and outlook to face the important questions bound up with the future of the health services of the city, or whether it is to be content to have as its medical officer of health the type of man who will be content to accept such an office in face of the unanimous opposition of the organized medical profession to its terms of employment. As has been stated previously, Manchester will almost certainly be able, should the corporation insist, to appoint a medical officer of health with the bare requisite qualifications, in spite of the British

Medical Association, the Society of Medical Officers of Health, and the opposition of the medical press. The more that is known about the position that awaits the medical officer in Manchester the more may it be wondered how far desirable for the good of the city such an appointment would be.

Retirement of Mr. R. W. Harris from the Ministry of Health.

The name of Mr. R. W. Harris is very well known to all insurance practitioners, and as Assistant Secretary in charge of the National Health Insurance Medical Benefits Department of the Ministry has necessarily come frequently in contact with the Insurance Acts Committee. It having come to the knowledge of the Committee that Mr. Harris had offered himself as a voluntary sacrifice to "the Geddes axe" and was retiring very shortly, an opportunity was taken on February 2nd, when the Insurance Acts Committee met representatives of the Ministry in conference, to express to Mr. Harris the kindly feelings which the members of the Committee have for him. The chairman (Dr. Brackenbury) said that he desired on behalf of himself and the Committee to say how sincerely they appreciated the manner in which Mr. Harris had dealt with them on those occasions when, in conference with him, they had had to consider National Health Insurance matters. They had come to look upon him not only as a firm and fair-minded administrator but also as a friend, and he desired to record their very great appreciation of his many kindnesses and to express the hope that he would have the best of health in which to enjoy his retirement. Dr. Cox, on behalf of himself and his colleagues, associated himself with this tribute, and said that though often in the course of their duty they had had to disturb Mr. Harris in that atmosphere of ease and serenity which was traditionally associated with the Civil Service, they had always found him an exceedingly courteous opponent when it was his duty to oppose, and very helpful on the numerous occasions on which his advice could properly be given. Above all Mr. Harris had always been a perfectly straight dealer. Mr. Harris, in reply, said that he would carry the words that had been said about him into his retirement with much appreciation. He had been associated with the National Insurance system since the day the 1911 bill was introduced. He had always endeavoured to be fair and straight and would always feel that the most interesting portion of his work in the Civil Service had been that in connexion with National Health Insurance. Sir Arthur Robinson, Secretary of the Ministry, who was in the chair, said that he had listened with great pleasure to what had been said about his colleague, and would certainly pass it on to the Minister. As secretary it was his duty not only to administer the National Insurance system, but to see that it was done with as little avoidable friction as possible, and in that spirit when Mr. Harris went he would endeavour to make such arrangements as would continue the atmosphere of good feeling which had generally prevailed in connexion with National Insurance negotiations. He announced that Mr. L. G. Brock, C.B., Assistant Secretary, would take Mr. Harris's place.

SCOTTISH COMMITTEE.

A MEETING of the Scottish Committee of the British Medical Association was held at 6, Rutland Square, Edinburgh, on Thursday, January 26th, 1922. There were present Dr. R. A. Bolam (Chairman of Council), Dr. W. Snodgrass (Chairman of Scottish Committee), Drs. R. C. Buist, J. Stevens, D. Lawson, F. K. Smith, J. Ritchie, G. W. Miller, J. B. Miller, H. Miller, R. Thin, and J. D. Comrie, with the Scottish Medical Secretary, Dr. J. R. Drever.

It was resolved to appoint Dr. John Patrick, Glasgow, a member of Committee in place of Mr. Grant Andrew, resigned.

Fees for Attendance at Maternity and Child Welfare Clinics.

A reply was submitted from the Board of Health to the letter sent, on behalf of the Committee, asking them to sanction a fee of one guinea per session where such session does not ordinarily exceed one hour's duration. The Board cannot agree to recognize a uniform fee or scale of fees, being of opinion that the fees should not be based solely on the duration of a session. They point out that the fixing of fees is primarily a matter for local settlement.

"But the Board, when it is reported that the sum proposed to be allowed is inadequate to secure an efficient service, are willing

to consider the special circumstances." . . . "I am to add, with regard to the fees at present in operation, that the recent substantial fall in the cost of living represents in effect an increase in these fees."

The Committee noted with satisfaction that the Board have apparently resiled from their former attitude, as expressed in their letter to local authorities, intimating that they were not prepared to approve of a fee in excess of 13s. 4d. per hour. Further, it was reported to the Committee that the fee of one guinea is now being paid in some areas. It was resolved that a reply be sent to the Board pointing out that the fee of one guinea, as fixed by the Committee, bore no relation to alterations in the cost of living, and represented the minimum fee for which practitioners should be expected to undertake work of this sort, and offering to co-operate with the Board in securing an efficient service, provided an adequate fee is paid.

Membership of the Association in Scotland.

It was reported that the canvass of non-members was being taken up heartily by several Divisions, and that others were only prevented from doing so by the present epidemic.

Existing Public Provision of Medical Services.

The Committee considered a report of the Chairman's Subcommittee, giving a detailed account of the powers possessed by local authorities in Scotland for providing medical services. It was resolved to circulate the report to Divisions, and to institute an inquiry into the nature and extent of the provision that is made locally, under the various heads, in each area, with the view to a conference of Scottish Representatives being held to consider the whole question.

Medical Examination of Railway Employees.

The Committee considered the following paragraph from the Award of the National Wages Board on the claims of the Scottish Railways:

"The railway companies shall take steps to ascertain at the time of engagement or as early thereafter as practicable, whether each new entrant to the service is likely to prove an efficient employee from the point of view of physical and mental suitability, in order to prevent as far as possible the necessity for dismissal on these grounds when he reaches the adult age."

It was resolved to recommend to the Council of the Association to consider the conditions under which such medical examination should be conducted.

SOUTH AFRICAN COMMITTEE.

A MEETING of the South African Committee of the British Medical Association was held in Cape Town on October 10th, and continued on October 15th, 1921, with the President, Dr. W. WATKINS-PITCHEFORD, in the chair.

The Referendum.—It was resolved:

"That, in view of the fact that the Referendum was contingent upon federation with the British Medical Association, and that the decision on the question of federation has been postponed for another year, this Committee is of the opinion that no steps should be taken towards the formation of a new Association until the question of federation is definitely decided by the parent Association; and that this opinion be communicated to Congress."

Remuneration of Medical Men in Government Employ.—

As a sequel to the interview between the Secretary for Public Health and delegates from this Committee on April 1st last, a letter had been received from Dr. J. A. Mitchell, taking exception to the "inaccuracies and ambiguities" in the report of the interview as published in the minutes of this Committee. It was resolved:

"That this Committee regrets that the Secretary for Public Health has had occasion to take exception to the wording of this report, which was published as a bona fide account of the interview."

A letter dated April 4th, 1921, from Dr. Cox, Medical Secretary of the British Medical Association, was read. This letter referred to certain statements with regard to the remuneration of Government medical officers in South Africa, such statements having been made to Dr. Cox by "a member." Dr. Cox asked whether the matter had been considered by this Committee, offering, if it should be deemed desirable, the services of the BRITISH MEDICAL JOURNAL to make public comment upon the inadequacy of the official remuneration. Dr. Cox drew special attention to the assertion that medical inspectors were inadequately paid, as compared with officers doing administrative work in the Department of Public Health, or with similar medical appointments in other parts of the world.

After general discussion and detailed inquiry and report by two members of this Committee, it was resolved:

"That a copy of the last minute dealing with this subject (Meeting of March 31st, 1921) should be sent to Dr. Cox, and that he should be informed: (1) That the remuneration of the officers in question has been increased, and that this Committee is informed that all possible efforts are being made to obtain further increases; (2) that this Committee considers that the lowest salary for a medical officer requiring special knowledge or qualifications should be paid to such officers as are paying assistant health officers more or less than inspectors, and considers this matter to be one of departmental concern only, so long as the minimum of £1,000 is adhered to."

It was reported that a deputation from the O.F.S. Union met the Minister of Public Health (Mr. P. Duncan) in Bloemfontein, on August 28th, 1921, to discuss with him the grievances of district surgeons. One of the members of this Committee, Dr. S. M. de Kock, had associated himself, at the request of the President, with this deputation, and had expressed the entire sympathy of this Committee with the movement.

Customs Dues on Laboratory Apparatus.—The attention of the Committee was drawn to the following anomaly in the Customs Regulations:

Surgical instruments are admitted without duty, but microscopes and their accessories, together with all other apparatus required for the diagnosis and study of disease, are heavily taxed. The tariff shows that surgical instruments and apparatus for diagnosis and research are not specimens mentioned, they are automatically relegated to Class VI ("general"), and upon all such articles a charge of 20 per cent. ad valorem is made.

The following resolution was passed for submission to Congress, which subsequently unanimously adopted it:

That the attention of the Honourable the Minister of Public Health and of the Commissioner of Customs and Excise be called to the fact that laboratory apparatus, microscopes and their accessories, and all other apparatus and material required for medical diagnosis and research are subject to duty upon entering the Union; whereas surgical instruments are admitted duty-free. And—that an adjustment of this anomaly is requested in the interests of public health.

Addington Hospital.—A request from the Council of the Natal Coastal Branch for advice concerning the propriety of the charging, by Addington Hospital, of fees for surgical operations carried out by salaried officers at the hospital, was received and considered. A letter which had been addressed by the Secretary of the Branch to the Provincial Secretary, Natal (August 22nd, 1921), was read to the meeting. The President stated that he had requested the confidential opinion of Dr. R. P. Mackenzie, of the Johannesburg Hospital, upon the position as disclosed by the Council of the Natal Branch, and Dr. Mackenzie's considered opinion was read to the meeting. The following resolutions were passed:

1. That the Natal Coastal Branch should be advised to press for the following arrangements:

- (a) That an honorary visiting staff be appointed to Addington Hospital, Durban, to attend to non-remunerative patients; and
- (b) That remunerative patients should be attended by their own medical men.

2. That any steps taken in this direction by the Natal Coastal Branch will have the full support of this Committee.

Provincial Tax upon Medical Practitioners.—It was reported to the Committee that, since its interview with a member of the Cape Provincial Council in April last, the levying of a special impost upon medical men had been given effect to in the form of a taxing ordinance. The memorandum which had been prepared by a member of this Committee for circulation to members of the Cape Provincial Council was now considered by this Committee. It was resolved:

"That, as a protest against a renewal of this impost in the form of a Taxing Ordinance, a suitably modified copy of the Memorandum should be sent to each member of the Cape Provincial Council."

Disciplinary Powers.—Certain correspondence was read between Dr. Campbell Watt and the Medical Secretary, London, respecting enlargement of the disciplinary powers possessed by this Committee. His action, which asked the Medical Secretary to promise to bring the matter up before the Central Ethical Committee, was approved. It was pointed out that no enlargement of powers would become operative before the sanction of the Branches of the British Medical Association in South Africa had been given thereto.

Chartered Society of Massage and Medical Gymnastics.—A letter was presented by a Natal member, signed by seven members of this society (late I.S.T.M., of London), drawing the attention of the medical profession of South Africa to the existence of their society, which was the only one recognized

in Great Britain. The signatories solicited the protection of the profession on the grounds that members of their society are prohibited from treating patients except with medical sanction. They pointed out that, owing to lack of legislation in this country, there are many practitioners of their speciality who treat patients on their own responsibility.

It was resolved:

"That this Committee expresses its sympathy with the aims of the Chartered Society, and that all members of the Council of Public Health should be informed of the desirability of supporting the provision (Clause 32) made in the new Medical Bill for the training and registration of masseurs and masseuses."

Trained Nurses' Association.—A deputation representing the South African Trained Nurses' Association was received by the South African Medical Congress at its second business meeting on October 14th, 1921. The deputation solicited the sympathy and support of the medical profession with regard to the following matters:

(a) The undesirability of employing untrained women as nurses and midwives; (b) the undesirability of employing midwives in general cases, and of nurses without midwifery training in obstetrical cases; (c) the undesirability of training probationers in nursing homes; (d) the desirability of increasing the number of personally conducted cases from 5 to 15 for the midwifery certificate of the Colonial Medical Council (of the Cape Province); and (e) the undesirability of permitting lady attendants in doctors' and dentists' consulting rooms to wear the uniforms of trained nurses and to be addressed as "sister" or "nurse."

These representations having been remitted by Congress to the Committee, it was resolved that the fullest practical publicity should be given to them with the aid of the medical press.

Meetings of Branches and Divisions.

EDINBURGH BRANCH: SOUTH-EASTERN COUNTIES DIVISION.

AN ordinary meeting of the South-Eastern Counties Division was held on February 1st at Newtown St. Boswells, when Dr. P. J. HENDERSON, Chairman of Division, presided.

The CHAIRMAN made a reference to the severe loss the Division had sustained in the death of Dr. Cullen of St. Boswells; they had lost a most valuable member. Few took a greater interest in the work of the Association, and few were so able to put the work through. The members respected his attainments and high character, and his genial presence would be much missed amongst them. The Secretary, Dr. Oliver, was instructed to convey to Dr. Cullen's widow and family an expression of sympathy. He said that on the suggestion of the Chairman he had sent a wreath on behalf of the Division at the time of the funeral.

On the motion of Dr. SOMERVILLE, seconded by Dr. McMILLAN, it was agreed that the Representative in Representative Body should be elected at the next meeting of the Division. The Secretary was instructed to construct a card index of all practitioners, and to send cards containing particulars of non-members to members of the Executive Committee and others with a view to each non-member being personally canvassed.

The SECRETARY reported communications received regarding the case *Claydon v. Wood-Hill*, and was instructed to circularize members so that they should have the opportunity of showing their sympathy with Dr. Wood-Hill as a means of expressing their antipathy to such actions against medical practitioners engaged in the honest exercise of their profession.

Dr. EDWIN BRAMWELL, having been introduced by the Chairman, then delivered an address on "The Scope and Limitations of Psychotherapy in General Practice." At the conclusion there was a short discussion, chiefly contributed by Dr. STEELE, who was of opinion that there were few patients admitted to asylums who had not got beyond the stage in which psychotherapy was useful.

At the conclusion of the paper a hearty vote of thanks was, on the motion of the CHAIRMAN, accorded to Dr. Bramwell for his very interesting address.

LANCASHIRE AND CHESHIRE BRANCH: MID-CHESHIRE DIVISION.

THE report of the Executive Committee for the year 1921 states that the work of the Division has been smoothly carried on. The meetings were on the whole well attended, nearly 50 per cent. of the members attending at least one meeting. Matters of importance affecting the Association in general and the Division in particular were discussed and action taken where indicated. The average attendance at each meeting was 13.5, and the number of members who attended at least one meeting was 30. Seven meetings of the Executive Committee were held, with an average attendance of 7.7. Special interest attached to the annual meeting, which was attended by Dr. Alfred Cox, the Medical Secretary, who was accompanied by Dr. T. W. H. Garstang, the Chairman of Representative Body. Dr. Cox delivered an address on "The claims of the British Medical Association on every section of the medical profession."

The Division took active steps to support the ultimately successful opposition of the Association to certain clauses of the Dangerous Drugs Regulations. The Medico-Ethical Association

of Manchester having published a tariff of medical fees for the use of its members, the Division discussed it and, with certain reservations, adopted it as a guide.

Dr. T. W. H. Garstang, the Division's Representative, gave an address on April 17th on the proposed federation scheme of the British Medical Association. At the meeting held at Northwich, Dr. Peyton, the county tuberculosis officer, delivered an interesting address on the "Policy and outlook in regard to the tuberculosis problem in Cheshire."

METROPOLITAN COUNTIES BRANCH: CITY DIVISION.

THE second Divisional dinner-dance was held at the Abercorn Rooms, Great Eastern Hotel, on February 2nd. The CHAIRMAN, Dr. C. E. Evans, and his wife, received the guests, numbering between seventy and eighty. A thoroughly enjoyable evening was spent, the dinner being excellent and the dance heartily entered into. It was a financial success. The next dinner-dance—the last of the year—will be held at the same place on Thursday, March 30th, when fancy dress will be optional.

NORTH OF ENGLAND BRANCH: CLEVELAND DIVISION.

THE annual dinner of the Cleveland Division was held in Middlesbrough on February 2nd. Mr. W. S. DICKIE, F.R.C.S., Chairman of the Division, presided, and was supported by the Vicar of Middlesbrough, the Mayor of Middlesbrough, and the Clerk to the North Riding Insurance Committee. Fifty-three members and guests were present and a very enjoyable evening was spent. After an excellent dinner the CHAIRMAN gave the toast of "The King." Dr. BODY proposed "The Town and Trade of Middlesbrough" and the MAYOR suitably replied. The toast of "The Cleveland Division" was proposed by Mr. W. EDWARDS, M.A., in a humorous speech, and the CHAIRMAN, in his reply, effectively countered many of the shafts of wit which had been directed by the proposer against the medical profession. Dr. W. STEEL gave "Sister Professions," the VICAR OF MIDDLESBROUGH responding in a happy speech. Dr. HOWELL proposed "The Guests," on behalf of whom Mr. W. R. BRACKENBURY and Mr. C. POSTGATE replied.

Mr. W. Brett, Mr. C. Mildred, Mr. Sulley, and Dr. W. B. Jones contributed to the harmony of the evening, which was brought to a close by the singing of the National Anthem, followed by "Auld Lang Syne."

SOUTH MIDLAND BRANCH: BEDFORD DIVISION.

A GENERAL meeting of the Bedford Division was held at the Bedford County Hospital on January 31st; Dr. KILHAM ROBERTS being voted to the chair.

The HONORARY SECRETARY reported that the Beds County Education Authority and the Bedford Borough Education Committee had refused to pay for medical certificates for children attending elementary schools. The Luton Borough Education Committee had merely acknowledged receipt of the latter. He further reported that he had been in communication with the Beds County Council with reference to payment of travelling expenses of medical men attending coroners' inquests, and they had appointed a small subcommittee to meet a deputation from the Division to discuss the matter.

The meeting then considered the annual report of Council and resolved:

That this Division approves of the recommendations contained in that report.

The meeting then discussed the proposed reduction in the dispensing capitation fee. It was the feeling of the meeting that the proposed reduction was quite uncalculated for, and the following resolution was passed:

That any reduction of the 2s. capitation dispensing fee would be absolutely unfair, and would amount to a distinct breach of faith, and this Division strongly supports the Insurance Acts Committee in any steps they may take in this matter.

The meeting decided to issue an appeal to all members of the Division asking them to support the Wood-Hill fund.

Dr. BRYDEN GLENDINING read an interesting paper on the diagnosis of gastric ulcer, illustrated with numerous x-ray plates. He confined himself to the special tests now used. (1) The benzidine test for occult blood in the faeces; (2) chemical analysis of the stomach contents, with special regard to the estimation of free hydrochloric acid, and of the total acidity; (3) the interpretation of x-ray photographs. He pointed out the more important characteristic appearances, such as niches, or bud-like protrusions due to the bismuth entering the base of the ulcer; hour-glass contractions, with the distinction between the organic and spasmodic; delayed emptying of the stomach; hypotonus or sagging of the viscus, and altered peristalsis. A hearty vote of thanks was passed to Dr. Glendining for his very instructive paper.

YORKSHIRE BRANCH: SCARBOROUGH DIVISION.

A MEETING of the Scarborough Division was held on January 26th. After the local business had been transacted the rules suggested for adoption by a Division not itself a Branch were discussed and amended, and the Honorary Secretary was instructed to forward a copy for the consideration of the Central Council.

The following resolution was passed unanimously:

The Scarborough Division of the British Medical Association view with grave concern the fact that the city of Manchester are offering a salary of only £1,500 per annum for the post of medical officer of health, and express the hope that no medical officer will apply.

Association Notices.

TABLE OF DATES.

- Feb. 11, Sat. Last day for receipt at Head Office of Nominations, by not less than 3 members, for election of 7 Members of Council for 1922-23 by grouped Oversea Branches.
- Feb. 15, Wed. Council Meeting, 429, Strand, at 10 a.m.
- Mar. 15, Wed. Branch Reports for 1921 due to Head Office on or before this date.
- April 1, Sat. Nomination papers available at Head Office for election of 24 Members of Council for 1922-23, by grouped Home Branches.
- April 26, Wed. Council Meeting, 429, Strand, at 10 a.m.
- April 29, Sat. Last day for receipt at Head Office of Independent Motions for Annual Representative Meeting. Agenda as to policy, Articles, or By-laws (By-law 40).
- May 6, Sat. Annual Report of Council appears in SUPPLEMENT.
- May 8, Mon. Last day for receipt at Head Office of Nominations, by a Division or not less than 3 Members, for election of 24 Members of Council by grouped Home Branches for 1922-23.
- May 13, Sat. Publication in SUPPLEMENT of list of nominations for election of 24 Members of Council by grouped Home Branches for 1922-23.
- May 27, Sat. Last day for receipt at Head Office of voting papers for election of 24 Members of Council by grouped Home Branches. (Where there are contests.)
- June 3, Sat. Publication in SUPPLEMENT of results of Council elections by grouped Home Branches.
- June 10, Sat. Nomination papers available at Head Office for election of 12 Members of Council by grouped Home Representatives.
- June 14, Wed. Council Meeting, 429, Strand, at 10 a.m.
- June 23, Fri. Last day for election of Representatives and Deputy-Representatives.
- June 24, Sat. Supplementary Report of Council appears in SUPPLEMENT.
- June 30, Fri. Last day for receipt at Head Office of notification of election of Representatives and Deputy-Representatives.
- July 7, Fri. Last day for receipt at Head Office of Amendments and Riders for Annual Representative Meeting Agenda.
- July 21, Fri. Annual Representative Meeting, Glasgow, 10 a.m. Nominations for election of 12 Members of Council by grouped Representatives to be received at Annual Representative Meeting, Glasgow, by this date.

BRANCH AND DIVISION MEETINGS TO BE HELD.

EDINBURGH BRANCH.—The winter clinical meeting of the Edinburgh Branch will be held in the Royal Infirmary on Friday, February 17th. All members of the profession are cordially invited. The Museum will be open from 11 a.m. Arrangements will be made for holding special clinics during the forenoon. The clinical meeting will be held at 3.30 p.m. Dinner at 6.30 p.m. in the Caledonian Station Hotel; morning dress; dinner ticket, 1s. 6d. Members of the Branch are requested to notify the hon. secretaries not later than February 15th whether or not they intend to be present.

ESSEX BRANCH: MID-ESSEX DIVISION.—The Medical Secretary, Dr. Alfred Cox, will speak at the Bell Hotel, Chelmsford, on Wednesday, February 22nd, at 3.30 p.m., on the subject, "How the British Medical Association might be of more use to medical men." Questions will be invited at the end of the address. Non-members as well as members are cordially invited.

LANCASHIRE AND CHESHIRE BRANCH: SOUTHPORT DIVISION.—A meeting of the Southport Division will be held on Thursday, February 16th, when a B.M.A. Lecture will be given by Dr. A. Burrows on radium therapy.

METROPOLITAN COUNTIES BRANCH: CITY DIVISION.—A meeting of the City Division will be held at the Royal Northern Hospital, Holloway Road, to-day (Friday, February 10th), at 9.30 p.m. sharp, when Mr. R. C. Elmslie, M.S., F.R.C.S., Surgeon to St. Bartholomew's Hospital and the Royal Orthopaedic Hospital, will deliver a lecture on some practical points in the treatment of fractures. Lady members will be heartily welcomed.

METROPOLITAN COUNTIES BRANCH: WESTMINSTER DIVISION.—Nominations for the election of Representatives on the Council and Representative Body, and for members of the Executive Committee of the Division, should be sent to the Honorary Secretary, Mr. F. D. Bennett, 18, Savile Row, W.1.

NATIONAL INSURANCE PROBLEMS.

DEPUTATION TO THE MINISTRY OF HEALTH.

A DEPUTATION of the Insurance Acts Committee was received at the Ministry of Health on Thursday, February 2nd, by Sir Arthur Robinson, First Secretary of the Ministry, who was accompanied by Mr. R. W. Harris and Dr. J. Smith Whitaker, Sir Walter Kinnear, Mr. E. J. Strohmuenger, and others. The Insurance Acts Committee was represented by Dr. H. B. Brackenbury (chairman), Dr. T. Canning Askin, M.B.E., Dr. T. Ridley Bailey, Dr. H. S. Beadles, Dr. R. W. Craig, Dr. A. E. Cope, Dr. H. G. Dain, Dr. A. Forbes, Dr. P. V. Fry, Dr. E. A. Gregg, Dr. R. Wallace Henry, Dr. G. B. Hillman, M.B.E., Dr. E. Lewis Lilley, Dr. T. Wood Locket, Dr. H. F. Oldham, M.B.E., Dr. C. H. Panting, Dr. Frank Radcliffe, Dr. Andrew Smith, and Dr. J. P. Williams-Freeman, with the Medical Secretary and the Deputy Medical Secretary.

Sir ARTHUR ROBINSON stated that the Minister had received the case forwarded by the Committee (see BRITISH MEDICAL JOURNAL SUPPLEMENT, December 31st, 1921, p. 259), and asked whether the Committee had anything further to add.

Dr. BRACKENBURY stated that, having regard to the words of the Minister on October 15th, 1921, when dealing with the question of the remuneration of insurance practitioners, which were that "the arrangements in force as regards mileage and things of that kind, should remain in force as in the past," it had been assumed that there would be no reduction in the dispensing capitation fee. Apart from that point, to which the Committee attached great importance, it was felt that the case of a practitioner in an area where there was no chemist should receive generous treatment, as his case differed materially in many respects from that of the chemist.

Sir ARTHUR ROBINSON stated that it was necessary first of all to clear up the point as regards the Minister's words on October 15th, as they affected both the dispensing and mileage questions. The Minister regretted extremely that any misunderstanding or misconception existed in the minds of the members of the Committee as to the meaning of his words. The question had been discussed at the Ministry on several occasions as to whether, when the negotiations as to the new capitation fee were entered into, mileage and other things were to be included in one inclusive rate or whether the negotiations should be limited to the question of the reduction of the capitation fee. The Minister had finally decided to confine the negotiations at that stage to the one subject of the reduction of the capitation fee, and the words used were in that sense. The Minister had no thought whatsoever that he was giving any pledge that the position as regards mileage and dispensing would remain exactly as at present.

Several representatives of the Committee stated that, so far as they were concerned, when they left the deputation they were firmly under the impression that they knew the worst—that the Minister, in announcing the reduction of the capitation fee, had desired to state that other things would be left alone; and that there was no doubt that the Committee, the October Conference, and insurance practitioners generally, had taken the Minister's words as a declaration of the extent to which there was to be any interference with any kind of remuneration, and that that had been a material factor in the acceptance of the reduced capitation fee.

Dr. BRACKENBURY said that they were content to rely on the words quoted from the agreed report. These seemed quite clearly to mean something more than that there were to be separate mileage and other funds. They imply that the arrangements for calculating these funds shall remain as before.

The representatives of the Ministry reminded the Committee that the "arrangements" with regard to mileage implied that the report of the Distribution Committee would be awaited before the Minister was in a position to deal with the subject, and that the question of the appropriate capitation fee for drugs was one which, as hitherto, would require to be the subject of separate negotiations after the Minister had considered the representations of the pharmacists in the matter.

Sir ARTHUR ROBINSON finally regretted the misunderstanding that had arisen, but expressed the opinion that the words used as set forth in the agreed report were in accordance with the position taken up by the Minister, as stated by him

above. The views of the Committee would, of course, be brought to the notice of the Minister, but it did not appear to him that the matter could be carried any further.

DISPENSING CAPITATION FEE.

Sir ARTHUR ROBINSON stated that the negotiations between the Minister and the pharmacists were still going on, and that until they were carried a little further no useful purpose could be served by discussing the dispensing doctors' position. In any event, no alteration in the present arrangements could now take place on April 1st.

Dr. BRACKENBURY stated that it must be clearly understood that the Insurance Acts Committee did not admit that the position of the dispensing doctor should be governed by the settlement between the Minister and the pharmacists.

MILEAGE.

Dr. Brackenbury stated that it was desired to deal with the mileage question in two portions—namely, ordinary mileage and the "reserved portion," for specially difficult areas. The Committee agreed that the reduction for 1921-22 of the amount available for ordinary mileage was compatible with the statement made by the Minister on October 15th, inasmuch as the distribution of the mileage grant for 1920 had been largely based on assumptions and guesswork, whereas the proposed distribution for 1921-22 was governed mainly by calculations based on returns made from the various areas. But with regard to the "reserved portion," the opinion of the Committee was that the Minister had acted contrary to the promise he had given in October 15th, and against the recommendations of his own Distribution Committee, inasmuch as the latter said in its report dated November 28th, 1921:

"With regard to the portion of the fund reserved for cases of exceptional difficulty, since the amount credited for 1920 to the different committees was based on a direct examination of the areas concerned, there does not appear to be the same necessity for a revision of the amounts allotted for these special cases. We are informed that some additional claims for cases of special inaccessibility have been received by the Department, and we consider that these further claims, which are in the aggregate small in proportion to those already considered, should be assessed on the same basis as the special claims submitted for the year 1920."

The representatives of the Committee urged that, in any event, an explanatory statement should be issued for the information of insurance practitioners, showing much more clearly than did the letter of the Ministry of December 30th to Insurance Committees how the reduction in the total of the ordinary mileage had been arrived at, and that it would be an advantage if such report contained the figures for each area as to number of units, etc.

Memorandum with regard to the Mileage Fund, 1921.

Mr. HARRIS gave the following explanation with regard to the circular letter recently issued by the Ministry of Health, in which the following statement occurs:

"A portion of the Central Mileage Fund has been reserved for making payment in the case of areas of exceptional difficulty, and, as the basis of assessment of this part of the Fund is directly referable to the basis upon which the main portion of the Fund is calculated, the reduction in the main portion of the Fund has been reflected by a corresponding reduction in the reserved portion of the Fund."

In 1920 visits were paid by medical officers of the Ministry to the different areas from which claims had been received for special allowances for mileage in respect of districts of exceptional difficulty. The object of these visits was to report generally upon the special characteristics of the areas concerned, and to endeavour to deal with the claims in accordance with some uniform standard. It soon became clear that the only way to secure this uniformity of standard was to assume, as a basis of measurement, a unit of travelling on an ordinary country road and to reduce the difficulties of the special areas to a certain number of units so that, for example, walking over a footpath, crossing a stream, or covering a specially hilly district, would be regarded as equivalent to 4, 6, or some other number of units. This having been done, and the Distribution Committee having very fully considered the reports so furnished, they were enabled, on the unit plan, to make an assessment of the total number of special units which should be allotted to these areas of exceptional difficulty. The value of the unit having been determined, it was possible to convert the total number of special units into a sum of money which was allotted to the particular area affected.

The Distribution Committee recommended that for the year 1921 the main portion of the Mileage Fund should be calculated upon a basis of 1s. 1½d. a mile for the miles travelled in visiting insured, as distinct from private, patients, making an allowance for the proportion of this travelling which can properly be considered as covered by the ordinary capitation fee.

This sum of 1s. 1½d. produces, on the fuller information available for the year 1921, a Mileage Fund which, when divided by the total number of units representing the main portion of the Mileage Fund, produces a sum of about 1s. 10d. a unit. The value of the unit similarly ascertained in 1920 was 2s. 4d., and it will be seen that the reduction in the value of the unit from 2s. 4d. to approximately 1s. 10d. in the main portion of the Fund would necessarily be reflected by a reduction in the value of the unit in the specially reserved portion of the Fund, although the number of units allotted to each area in regard to the specially reserved portion of the Fund would remain unaffected, as having been determined after a consideration of the reports based upon an inspection of the areas concerned.

ADDITIONAL BENEFITS.

Dr. BRACKENBURY drew attention to the question of the provision of ophthalmic and other benefits now being arranged for by approved societies either directly or through the National Insurance Beneficent Society, and to the inquiry addressed by the Committee to the Ministry on January 28th, 1922, as to whether Section 14 of the National Insurance Act of 1911 did not provide that "all benefits of the nature of medical benefit" should be administered through Insurance Committees, and whether ophthalmic benefit, for example, was not considered to be of the nature of medical benefit.

Sir WALTER KINNEAR stated that according to the legal advisers of the Ministry any society using its surplus funds for direct provision of medical attendance and treatment would be acting against Section 14 of the Act of 1911, but that the additional benefits referred to as now being arranged for by approved societies were monetary payments of part or the whole of the cost of treatment obtained by members themselves, and not the organization of a service for them.

A lengthy discussion then took place, in the course of which representatives of the Committee expressed themselves as being quite unable to accept the view expressed by the Ministry.

It was contended that the question of whether an additional benefit was "of the nature of medical benefit" must depend upon the nature of the service provided and not upon the method of its provision.

Sir WALTER KINNEAR said that with respect to the payment of the whole or part of the cost of optical treatment given as an additional benefit, the Ministry was of opinion that this work should properly be performed by a medical practitioner, and in the model scheme which had been issued for adoption by approved societies they had inserted a clause providing that payments in respect of the cost of optical appliances should only be made on the production of a prescription from a qualified practitioner or a hospital, except where the claim was in respect of the renewal of an appliance. Out of some 410 societies and branches which had adopted the model scheme only 12 had declined to adopt this model clause.

TRANSFER OF PRACTICES.

The discussion of this question had been left at the conference between the Committee and representatives of the Ministry, on November 3rd, 1921, at the point where the Committee undertook to consider the suggestion made by the Ministry that perhaps there was no need for any allocation of insured patients at all, and that, if this was so, possibly no alteration of the Regulations would be necessary.

Dr. BRACKENBURY stated that the Committee was not prepared to recommend the acceptance of this suggestion, but was prepared to discuss with the Ministry a scheme which had been put forward by the Sheffield Panel Committee, without committing itself in advance to approval of that scheme.

It was agreed that the matter should be left to be dealt with in a preliminary way by a small number of representatives from each side.

POSTAGE ON MEDICAL RECORDS.

The Committee was asked for its views on the proposal of the Ministry that Insurance Committees should be authorized to make a small grant towards the expenses of Panel Committees instead of making the trifling payments to individual practitioners involved by the undertaking to allow insurance practitioners the extra cost of postage incurred in the transmission of records. Figures were given to show that the amount of money involved was so trifling as to make the clerical work involved in the transaction look absurd.

Dr. BRACKENBURY stated that though the Committee was not in a position to accept the suggestion it would place the proposal before the next Annual Conference. The Committee feared that the acceptance of any grant by the Panel Committee from the Insurance Committee opened up the possibility of interference by the Insurance Committee in the financial affairs of the Panel Committee.

It was agreed that if the Ministry could so frame the

THE DESTRUCTION OF VITAMINS.

THE two facts of greatest practical importance about vitamins are, first, that a certain minute supply of these substances is essential for animal life, and secondly, that they are very easily destroyed. It is most necessary to bear this second characteristic in mind, for the actual existence of vitamins can only be demonstrated by the disastrous effects produced by their absence from the diet or their presence in it in insufficient quantities; indeed, since vitamins occur naturally in nearly all fresh foodstuffs, it is probable that their existence would never have been suspected had they not been such unstable bodies.

As we have indicated in a recent article,¹ an abundant supply of vitamins exists in all fresh vegetable foods, and considerable quantities occur in milk and in meat, provided that the latter are obtained from animals fed on fresh foods. A normal adult living on an ordinary diet containing a reasonable proportion of fresh vegetables is, therefore, certain of obtaining a plentiful supply of vitamins. Unfortunately, these indispensable food constituents are, as has been said, very readily destroyed. All three vitamins are rapidly destroyed by heating in the presence of air or oxygen. Hopkins showed that the fat-soluble vitamin A in butter was completely destroyed by heating the butter to 120° C. for four hours if oxygen was bubbled through the butter, although practically no destruction occurred if the butter was heated without aeration. The experiment established the important fact that this vitamin, though fairly resistant to heat, is readily destroyed by oxidation. Zilva found that the antiscorbutic vitamin C was completely destroyed by boiling for an hour in the presence of oxygen, but that no destruction occurred when it was boiled for two hours in an atmosphere of carbon dioxide. The destruction of vitamins depends largely upon the length of time for which they are heated in the presence of air. Hess, for instance, showed that little destruction of vitamin C occurred when tomatoes were heated to 100° C. for fifteen minutes, but that four-fifths of the vitamin was destroyed when the tomatoes were heated to 100° C. for an hour. Similarly, it has been shown that a greater destruction of the vitamin C present in fresh milk occurs when it is heated to 60° C. for half an hour than when it is boiled for a minute. The reaction of the fluid containing the vitamin is also of importance, for vitamins are much more readily destroyed in an alkaline than in an acid fluid. The fluid need only be feebly acid. The antineuritic, water-soluble vitamin B is more resistant than vitamin C, but it also is readily destroyed by boiling in an alkaline fluid in presence of air.

A fair proportion of all three vitamins in fresh vegetables appears to survive ordinary cooking, but prolonged boiling, such as occurs in making stews, destroys nearly the whole of vitamin C, and probably most of vitamin A and B. The vitamins in milk are unfortunately very unstable; ordinary pasteurization destroys practically the whole of vitamin C, and a considerable amount of vitamin A.

The extraordinary difficulty of retaining vitamins in preserved foods is in large measure due to the fact that

vitamins slowly oxidize on keeping. Vitamin A is the easiest to preserve, for it appears to be fairly stable when dissolved in oil, and it can be kept in cod-liver oil for months and probably for years; it also survives for many months in tinned meat. Vitamin B can be preserved in the dry state, and wholemeal flour and unpolished rice retain their content of this vitamin for long periods. The preservation of vitamin C, the antiscorbutic vitamin, is by far the most difficult problem. This is well known; efforts have been made for the last hundred and fifty years to find some satisfactory way of obtaining a concentrated, portable, and stable preparation of the antiscorbutic element in fresh fruits or vegetables. The problem is of the greatest importance to the navy, and to explorers; in special circumstances it may be of first-rate importance to the army also. A stable preparation of vitamin C is essential for the prevention of scurvy when fresh vegetables and fruits are not obtainable. Lemon-juice was introduced as an antiscorbutic in the eighteenth century, and its use reduced the mortality in the navy enormously; lemon-juice is very rich in vitamin C, and the acids present help to preserve the vitamin. Unfortunately, in the nineteenth century lemon-juice was discarded for lime-juice, which has only one-quarter the vitamin content of the former. Lemon-juice, however, is not a really satisfactory vehicle for the preservation of vitamin C; Bassett-Smith found that commercial lemon-juice lost all its vitamin content rapidly; he showed, on the other hand, that dried lemon-juice tablets retained their vitamin for at least a year. Harden and Robison found that dried lemon-juice kept in a desiccator for fifteen months at room temperature only lost 50 per cent. of its activity. Hess ascertained that tinned tomatoes retained their vitamin C content with little loss for three years. He also found that if perfectly fresh milk was dried by a suitable process, and stored in sealed tins, its vitamin C content was preserved for many months. The simplest way of transporting vitamin C is by the use of dried peas; they contain little of the vitamin when dry, but produce large quantities when allowed to germinate; by the use of germinating peas an abundant supply of vitamins can be obtained by explorers or troops in sterile countries. It is important to realize that although dozens of different methods of food preservation are known, yet the few examples mentioned above are practically the only methods by which vitamin C can be preserved for any length of time.

Individuals living under normal conditions may suffer from vitamin lack, owing to an improper diet from which all vitamin-containing foods have been eliminated. All that is needed in such cases is the addition of such foods to the diet. The following foods are particularly rich in vitamins: Cod-liver oil contains about 240 times as much vitamin A as butter, yeast is the richest source of vitamin B, and fruit juices contain a large amount of vitamin C. Germinating seeds contain large amounts of both vitamin B and C, while green vegetables and tomatoes contain large quantities of all three vitamins. An abundant supply of all the vitamins can therefore be obtained simply by the addition to the diet of cod-liver oil and the fresh vegetables mentioned.

Certain workers claim to have produced concentrated preparations of vitamin B, but no methods are known by which either vitamin A or vitamin C can be obtained in concentrated form. Any attempt at chemical treatment produces a rapid destruction of the vitamins. As already pointed out, it is a matter of great difficulty to devise any means by which vitamin C can even be preserved, and its concentration is at present impossible. It is extremely easy to obtain an abundant supply of vitamin C by the use of fresh foods, but it is very difficult to retain more than a fraction of this vitamin in any form of preserved food. No substance is known

¹The Sources of Vitamins, BRITISH MEDICAL JOURNAL, January 21st, 1922, p. 115

which contains more vitamin A than cod-liver oil, and, as has been said, it is only in the case of vitamin B that any success has attended the repeated efforts that have been made to purify or to concentrate vitamins.

In spite of the fact that ordinary fresh foods are the simplest, cheapest, and richest sources of vitamins, the public apparently demands to be supplied with vitamins in the form of medicinal products. A large number of preparations are on the market which claim to contain vitamins. Some of these preparations are so far satisfactory that the prepared article has been proved to contain vitamins, although even in these cases a few ounces of green vegetables would probably contain more vitamins than large quantities of the preparation. In the case of certain manufactured products, however, it is simply stated that the preparation is made from substances very rich in vitamins. This statement means nothing, for, from the facts mentioned in this article, it is obvious that even if a preparation is made from a raw material rich in vitamins, it does not follow that the finished article will contain any vitamin at all when it reaches the patient.

We have endeavoured to state the known facts as plainly and directly as possible, and invite manufacturers to take note of them. They may be unwelcome, but they are, we believe, incontrovertible.

LUNACY REFORM.

THE Departmental Committee appointed by the Minister of Health to inquire into and report upon charges made against asylum administration by Dr. Montagu Lomax in his book, *The Experiences of an Asylum Doctor*, has been the subject of a good deal of criticism, and the position of the Committee has now been made very difficult by the refusal of Dr. Lomax, after at first consenting, to give evidence before it. He has taken this course, he states, because he considers that the Minister of Health had prejudiced the case by his speech at the recent Conference on Lunacy Administration, because the Mental Hospitals Association had extolled the system at present existing in its pamphlet (referred to in this JOURNAL of January 21st), and had thereby forestalled the Committee's verdict; and because the National Asylum Workers' Union had instructed its members not to give evidence owing to the one-sided and unrepresentative character of the Committee. Dr. Lomax stated further that he was acting on the advice of the National Council for Lunacy Reform, and criticized the constitution of the Departmental Committee on the ground that its members were all associated with the administration of mental hospitals. As an alternative he urged the appointment of a Royal Commission. In a reply to this letter Sir Alfred Mond pointed out that, pending such an extended inquiry as might be necessary at a later date, the appointment of a Departmental Committee was the most expeditious method of discovering the amount of truth there might be in Dr. Lomax's allegations. He regretted the action of the Asylum Workers' Union since the conduct of the members of the union had been criticized by Dr. Lomax in the gravest terms, and he pointed out that Dr. Lomax did not assist in the formation of a true verdict by publishing a large number of allegations and then declining to substantiate them.

As to the aims of the National Council for Lunacy Reform, its secretary, Mrs. Barbara Gould, states that its immediate object is "to secure for the mentally afflicted, both those who are certifiable under the present law and those who are not, treatment which shall be purely medical and curative—hospital treatment as opposed to asylum treatment. In pursuance of this purpose we shall resist the Board of Control's

policy of putting those in the early stages of mental instability into the atmosphere and conditions of the lunatic asylum." To this Sir F. J. Willis, Chairman of the Board of Control, has replied that the object of the Board is the same as that of the Council, and that to assert the contrary was untrue. He stated, furthermore, that, while recognizing that many of our institutions fall short of the ideal, nothing is more likely to check the spirit of progress than to cast obloquy on the work of those many men and women who are earnestly striving to do their utmost for the care and treatment of the mentally afflicted.

This brief survey will serve to indicate the present state of things. It must be recognized that the position of the Departmental Committee has now become one of considerable difficulty, and it is doubtful whether any conclusions at which it might arrive will have much weight with the public. In view of the fact that Dr. Lomax has refused to give evidence, and that the members of the Asylum Workers' Union have been instructed to adopt a similar attitude, it is difficult to see how the evidence on which the report should be based can be obtained. The situation is undoubtedly unfortunate, and there would appear to be some danger of the whole question assuming a political rather than a social aspect. The *Daily Herald* of February 4th publishes an account of an interview with Mrs. Barbara Gould, in which she states that the whole question is a matter for the Labour party to take up. It is, of course, a question for the Labour party, and every other party, to take up, and, as was pointed out in our leading article of last week, it is most desirable that the public as a whole should themselves take an intelligent interest in the problem of mental disorder.

Unfortunately, an impartial and careful survey of the correspondence to which reference has been made gives rise to the general impression that the National Council for Lunacy Reform is tending to assume an attitude of uncompromising opposition to any suggestion for reform emanating from the Ministry of Health, the Board of Control, the Mental Hospitals Association, or, indeed, anyone actually connected with the administration of asylums and the treatment of the insane. It is difficult to understand how such a policy can be effective in bringing about those reforms which may be desirable. The whole subject is extremely intricate; it is bound up with legal considerations and technical problems which can only be solved by those with an adequate appreciation of their difficulties. There appears to be an almost wilful tendency to misunderstand the aims, aspirations and suggestions of those actually concerned in the treatment of the insane, and a complete forgetfulness of the fact that the reforms which are now advocated have been the subject of discussion in the asylum world for several years. The contention of Sir F. J. Willis that the policy of the Board of Control is the same as that of the National Council for Lunacy Reform would seem to be perfectly just, and the letter published in our last issue, from Dr. Edwin Goodall, indicates an extremely enlightened policy, which has been adopted as part of the programme of the Mental Hospitals Association.

It is extremely important that the general public should support proposals for improvement in the conditions under which the insane are treated, but we feel that reforms will be achieved much more readily if those who are responsible for carrying them out receive the co-operation and support of the public than by an attitude of hostility and misunderstanding. As it is, there would seem to be a tendency by exaggerated statement to create a wrong impression of the atmosphere, treatment, and general conditions which exist in the asylum of this country.

EPIDEMIOLOGICAL STATISTICS OF EASTERN EUROPE.

THE assembly of the League of Nations decided last September that one of the functions of the Health Committee should be the organization of an epidemiological intelligence service. The Health Committee entrusted the work to the Health Section, which issued on January 14th its first report.¹ This report contains twenty-two pages of tabular matter, displaying the reported monthly incidence of typhus fever, relapsing fever, and dysentery in Eastern Europe for 1920 and 1921, and of cholera, enteric fever, and scurvy in Russia. Then follow several spot maps, statistical charts, and two notes, one on the incidence of disease upon the Red Army and the other on the Russian census. To judge from the diagrams relating to Poland of the Congress, the maxima of the successive epidemics of typhus in 1919-21 have declined. That of 1919 occurred in May, with over 31,000 cases; the maximum of 1920 was in January, with between 29,000 and 30,000. The diagram for 1921 shows a maximum in March, with about 10,000 cases. In Russia, on the other hand, the 1920 maximum greatly exceeded that of 1919. Cholera is widely disseminated through European Russia; mentioning only those governments which by October 29th, 1921, had notified at least 5,000 cases, we note the Ukraine, Voronej, Saratov, Samara, the Republics of the Bachkirs and Kirghiz, and Siberia. The Russian census commenced on August 28th, 1920, and the note on it is interesting. Comparative figures are only obtainable for the great cities and show large diminutions. Petrograd had fallen from 2,319,000 inhabitants in 1913 to 706,000, Moscow from 1,817,000 to 1,028,000, Saratov from 235,000 to 188,000. In the introductory note it is said that the "form in which this report is produced is by no means final. The most convenient method of producing charts and maps will be determined by the nature of the data that may be at the disposal of the Health Section in the future." For our part, we have some doubt whether the value of the data justifies the amount of typographical labour which has been expended upon them. Even in settled countries, statistics of incidence of infectious diseases are open to criticism and must be handled with great caution. Nobody, of course, would expect that statistics of notifications from Eastern Europe could do more than indicate the trend of events. The remarks on p. 39 of the report, where it is pointed out that no less than 43 per cent. of all scurvy cases and 46 per cent. of the relapsing fever cases were those returned by the military authorities, make us doubt whether even this limited value attaches to the Russian data. Yet an entire page of ten columns and forty-five rows is devoted to the notifications of scurvy in Russia. It also seems unnecessary to print the letterpress in both French and English. Few who consult these reports will be unable to read simple French. These comments are not intended to be depreciatory of the new venture, but one has to recollect that "official" statistics enjoy a certain prestige, and that they are often quoted by those who do not trouble to read the letterpress. Statistics cannot be made fool-proof, but when unreliable data are displayed in great detail there is some risk of avoidable error.

CANCER RESEARCH.

THE generous offers intended to stimulate cancer research made by Lord Atholstan and Sir William Veno have been directed into better channels since they were discussed in our columns on February 4th (p. 200). In response to the opinions publicly expressed by those in touch with scientific affairs, Sir William Veno immediately amended his offer, and has agreed to devote £10,000 to the direct and immediate assistance of cancer research during the next ten years in annual payments of £1,000. Lord Atholstan, in his turn, has stated that his first offer of a prize of 100,000 dollars (£20,000) for an "approved medicinal cure" for cancer still stands, but that he will give a second 100,000 dollars to help in the work

of research. The authorities of any particular institution are always apt to consider their own as that which is doing the most important work, but we think the head of one of the metropolitan hospitals has been a little precipitate in assuming that the funds thus unexpectedly accruing to the support of research work in cancer are meant exclusively for one institution. There is more than one laboratory for cancer research in this country. The Imperial Cancer Research Fund has an honourable history of some twenty years, and its record of achievement is not less than that of other similar bodies engaged in the same work. The London Cancer Hospital in the Fulham Road has a research institute, where much excellent work has been done, as has also the Royal Cancer Hospital, Glasgow. There are special cancer hospitals too at Liverpool, Manchester, Bradford, Dublin and Cork, all of them seeking a cure for the disease. There are also the radium institutes; that which has been established for a dozen years in London has done a great deal of valuable clinical work which has thrown light on the pathology and treatment of cancer, and it possesses also a research department; the Radium Institute at Manchester, established largely through the efforts of Sir William Milligan, has well-equipped research laboratories and a highly competent staff. All this is said not by way of disparagement of the cancer research laboratories of the Middlesex Hospital, which are probably the oldest in this country, and from which much first-rate work has emanated. We can quite understand that the authorities of the Middlesex Hospital should greatly desire additional funds to enable them to extend the scope of the researches there conducted, but what is wanted seems to be some impartial tribunal which will decide how the gifts now made can most advantageously be administered. It may well be that the Medical Research Council might most properly be entrusted with this duty; it is a committee of the Privy Council and receives a substantial grant from Parliament. This grant has recently been cut down; we gather, however, that the Council is continuing the assistance it gives to cancer research, and it would no doubt be in a position to advise as to the distribution of new money. It will be remembered that the Council is empowered under its charter to hold money derived from private benefactions.

THE LEAGUE OF NATIONS AND THE OPIUM TRAFFIC.

THE records of police and coroners' courts continue to bear witness to the extent of the abuse of drugs of addiction such as morphine, heroin, and cocaine, and remind us of the need for effective enforcement of the Dangerous Drugs Act, 1920. Some progress, though slow, has been made by the League of Nations towards putting into operation the International Opium Convention of 1912 since we last called attention to the matter.¹ Arising out of recommendations of the Advisory Committee and resolutions of the second assembly of the League last September the Council has directed certain important steps to be taken. Thus the Provisional Health Committee of the League has been moved to conduct an inquiry as to the actual amount of morphine, heroin, cocaine, and allied drugs which are deemed to be required for medical and legitimate purposes in different countries. Then, again, communications have been addressed to China, and to governments having treaty relations with China, with a view to stopping the illicit importation of dangerous drugs into that distracted country. Replies are, we understand, slowly coming in to the questionnaire addressed by the secretariat of the League to the various Powers parties to the Convention, as to the steps they have taken to put its Articles into operation, and also as to the illicit manufacture of dangerous drugs within their territories. It appears that there are several Powers which are now members of the League but which have not as yet signed the Convention, and several others which have signed it but not yet ratified it. The secretariat of the League has transmitted to all member States the recommendation urging that they should prohibit the export of any of the dangerous drugs in question to any country.

¹ *Epidemiological Intelligence: Eastern Europe in 1921*. No. 1. League of Nations, Health Section. Geneva, January 14th, 1922; pp. 53.

¹ BRITISH MEDICAL JOURNAL, August 27th, 1921, p. 329.

unless its Government shall have intimated its approval thereof and certified that such drugs are to be used for medical or legitimate purposes only. Questions dealing with the limitation of the world-production of raw opium to meet legitimate needs only, and as to the desirability of summoning a further international conference to consider the suppression of the abuse of all dangerous drugs, have been referred to the Advisory Committee, which is to hold its second meeting this spring; we are informed that April 25th has been provisionally fixed for its assembly. It is evident that much remains to be done in order to put into effective operation the provisions of the Convention of 1912 in regard to raw opium, opium prepared for smoking, morphine, heroin, and cocaine, and their salts and preparations, without at present embarking on a wider field. We have yet to learn that licences are required in this country for the manufacture of these drugs, or that any limitation is placed upon their production, as would appear to have been contemplated by the Dangerous Drugs Act of 1920. From a recent reply in the House of Commons it would seem that some 156,435 acres are under the poppy in British India, showing a more extensive cultivation than before the war. Nearly 1,600 chests of opium were exported from British India in 1919-20 to the Straits Settlements, Dutch East Indies, Siam, French Indo-China, Japan, Hong Kong and adjacent parts, and the Secretary of State is unable to say how much of this raw opium exported from India is converted into prepared opium for smoking. It would be interesting to know whether it is officially maintained that all the opium raised in India under Government control is required and utilized for medical and legitimate purposes only.

PHYSIOLOGY AND THE WAR.

It must be recognized that physiology is an independent science, and not merely a branch of medical science, and that all exact knowledge of the activities of life—human or animal—is founded upon it; without this exact knowledge medicine and surgery and preventive medicine would have remained in their mediæval stage of development. In the January number of *The Fight Against Disease*, the quarterly journal of the Research Defence Society, appears an article on "Physiology during the War," based upon the presidential address by Sir Walter Fletcher in the Section of Physiology at the Edinburgh meeting of the British Association last year. Modern physiology in this country may be said to have begun in 1836, with Sharpey's appointment to University College, London. To the influence of this great teacher may be traced directly the development of all the chief British schools of physiology. During the past half-century British physiologists laid the whole world under a heavy debt, and this period included the revolutionary work of Pasteur and Lister, which made a stronger appeal to the national conscience. During the war bacteriological work had its prominent place in the detection and prevention of disease, but in a sense the more complete the prevention of infective disease the more apparent became the stresses of war. The violent stresses offered in modern warfare to the human body—whether by physical damage through exertion and exposure, by terror or excitement, or by the stresses of flying and fighting in the air—brought many new and urgent calls for precise physiological knowledge. The results of pain and fear, of hæmorrhage, of shock by wound or operation, all required further analyses before effective treatment could be devised. Our forces being engaged in every climate, from the Equator to the Arctic regions, were faced with numerous local or accidental variations of diet, and it was necessary to apply physiological studies of heat-loss and of heat-production to the practical problems of clothing and diet. At home men and women alike were exposed to arduous toil and to poisons of many kinds needed for munitions, and in all these dangers the guidance of the physiologist was needed to avoid industrial fatigue and loss of output, and to devise methods of protection against industrial poisons. The menace of starvation threatened the whole

nation, and our escape from that was due to a system of rationing, based upon accurate physiological knowledge gained by experimental methods. Sir Walter Fletcher said that it would be a truism and a commonplace to affirm that no bravery and no fortitude could have avoided defeat without the help of scientific men and of the fruits of experimental science, though that commonplace had never been enshrined in the addresses or thanks of Parliament, or in the prayers and thanksgivings of the churches. The Research Defence Society exists to promote national health and efficiency, to bring about a better understanding of the value of medical and surgical studies, and to expose the false and frequently absurd statements often made against them. That this work is necessary may be seen from the crude prejudices and sentimental appeals of such "antivivisection" publications as the *Abolitionist*, a British antivivisection magazine, the scientific value of which may be gauged from such an editorial comment as the following: "The only disease to which cow-pox bears analogy is that of syphilis. It is urged that cow-pox is not now taken from child to child, but is passed through a calf, and that the introduction of human diseases is therefore impossible; but the origin of the matter inoculated into the calf is unknown and its history is a very shady one" (*Abolitionist*, January 2nd, 1922, p. 7). The Research Defence Society, which defends medical studies and exposes the false statements that are made against them to the public, deserves to be supported by the medical profession. The annual subscription is 10s., and applications for the society's publications should be sent to the secretary, 11, Chandos Street, London, W.1.

A PHYSICIAN ON THE SURGICAL TREATMENT OF EMPYEMA.

Is a refreshingly frank paper, largely based on the application of knowledge gained during the war, about wounds of the chest, to the routine treatment of thoracic empyema, Dr. J. A. Nixon, of Bristol, has pointed out that it is the physician's duty to improve the commonly practised treatment of empyema, which consists in opening and drainage by a tube. The procedure, comparable to opening an appendix abscess and insertion of a drainage tube, should, whenever possible, be avoided, for secondary infection readily supervenes, thus increasing the danger to life, causing increased interference with re-expansion of the lung, and retarding convalescence more than do most single infections. It has long been known that pneumococcal empyemas sometimes clear up entirely after aspiration alone, and this satisfactory result would probably be much more frequent if aspiration was performed earlier and for smaller collections of fluid than is the usual practice. The experience gained in the later part of the war from the influenza cases, both in Europe and America, was that early resection for streptococcal empyema was disastrous, and that repeated aspirations either led to cure or tiled the patients over until an operation could be safely undertaken. The operation, it is urged, should consist of a wide incision so as to allow good access to, and inspection of, the pleural cavity and its exploration with the hand for the removal of lymph. In order to favour expansion of the lung, the chest should be completely closed at the operation and resection of ribs should be avoided; if necessary, repeated aspiration can be performed subsequently. Dr. Nixon looks forward to the time when open drainage of the chest will be regarded in the light of "a surgical abomination," and points out how rapidly a collapsed lung will expand; in one case the lung was found to have expanded completely two hours after complete thoracotomy with hermetic closure of the wound. When the pleural cavity is properly cleaned the lung readily expands and is not prevented from doing so by the presence of air; for this reason breathing exercises, such as blowing into bottles, are unnecessary; in the presence of adhesions they are useless. Decortication of the lung should, if it is to be performed, be carried out at the time of the primary operation and not be regarded as essentially a late

procedure. The lung can be handled without producing shock if care be taken to prevent displacement of the mediastinum and its contents; but if the heart is allowed to swing out of position very grave shock may result. In this connexion it is interesting to note how very little distress is caused by sudden pneumothorax when the heart is retained in position by old adhesions. The procedure designated by Tuffier as "Estlander's ill-advised operation" is defined by Dr. Nixon as "a belated confession of a series of therapeutic failures"; it appears to be based on the assumption that since the lung has collapsed the best that can be done is to accept the situation and make the chest wall also collapse. Collapse of the lung should be prevented by thorough exploration of the pleural cavity at the time of operation or as early as possible when it appears probable that the lung is not expanding. If this becomes the practice, Estlander's thoracoplasty, which merely sets a seal on an embarrassing deformity, will fall into the complete oblivion it deserves.

MEDICINE IN THE "ENCYCLOPAEDIA OF RELIGION AND ETHICS."¹

As each volume of this great work has appeared it has been the practice to note here some² of the articles which have had medical matters as their subject, or which have been more or less directly related to medicine. The work is now crowned by the issue of the twelfth and last volume, and the highest compliment which can be paid to the editor (James Hastings, M.A., D.D., Aberd.) and his assistants and his publishers (T. and T. Clark, Edinburgh) is that the high level reached by the earlier instalments has been maintained fully. On an average each volume has contained over 900 two-columned pages, and the type, never large and often rather small, has conspired with the editor to crowd many more words into each page than a mere glance at the work would suggest. Thus there are here over 10,800 pages, or 21,600 columns, with at least 600 words in each column, or a grand total of more than 12,960,000 words; and there is no padding. It is a stupendous work; it is nothing less than a national achievement comparable to the *Dictionary of National Biography* or the *New English Dictionary*; it has been accomplished within fourteen years. To the medical man the concluding volume, like all its predecessors, offers many articles of interest. Even the first of them on Suffering, although not strictly medical, cannot but draw his attention, for it deals particularly with the problem of "meaningless pain," the riddle which is untely or articulately asked of many doctors every day. There is something, too, of medicine in the articles on the Todas and the Veddas, both of them written by Fellows of the Royal College of Physicians of London (W. H. R. Rivers and Charles G. Seligman); but there is much more in several of the articles from the pens of non-medical authors. In the latter category comes the article on Sweat and Sweat House; a fact which may account for the slip with which it begins—namely, "sweat is a secretion of the sebaceous glands," sudoriparous, of course, being intended. Dr. Edwin Sidney Hartland's articles on Totemism and on Twins are most attractive; indeed, in that on twins the President of the Folklore Society has brought together and made a readable article of a great mass of extraordinary facts bearing upon the notions and superstitions that are to be found in every part of the world on the subject of plural births. To dip into it at random, one finds this: "In Mexico the Tlaxcalans call twins snakes; and they are believed able to cure the bites of serpents and other animals, as well as pain or inflammation of the tendons, especially of the feet and ankles; triplets will be kings." But in too many places twins are held to be unlucky and are destroyed. In India the birth of twins of different sex is a serious matter; their close association in the uterus has been sinful. "In

the north-east of Scotland twins are so far regarded as unlucky that one of them, even though married, will be childless." Other articles touching on medicine are those on vegetarianism and on vivisection. The summing-up of the latter (which is by Geikie-Cobb, D.D.) is, "the method of regulation, not suppression, adopted in this country does justice at once to the unquestioned claims of the lower animals to kindly treatment and to the duty of man to his fellows—the duty of using his reason in the age-long task of diminishing and finally extinguishing that particular form of evil which goes by the name of disease." There is something, too, of medicine in the articles on suggestion, suicide, sun, moon, and stars, Swedenborg, talu, the Tati bushmen, tattooing, teeth, temperament, temperance, the Tlingit, the Tongans, Touking, transmigration, the Tungus, nelson, vampire, Vancouver Island Indians, water, will, the Yakut, yawning, and the Yogis (and their hypnotic devices). Wherever the volume is opened something of interest is found. An index volume is in preparation, and will add greatly to the value of the whole work.

THE COLLEGE OF SURGEONS IN 1822.

FEBRUARY 13TH, 1822, is one of the landmarks in the history of the Royal College of Surgeons of England, for that was the date on which George IV granted it a supplemental Charter, changing the titles of the principal Master and Governors to President and Vice-Presidents, and providing that the Court of Assistants should in future be styled the Council of the College. The last Master and first President was Sir Everard Home, the pupil and assistant of John Hunter, whose sister he married. The "indelible blot" on Home's fame is his destruction of Hunter's manuscripts. The Charter of 100 years ago further empowered the College, "at all times hereafter, and upon all such occasions as they shall think proper and expedient, to exercise and enjoy the Right and Privilege of having a Mace, and of causing the same to be borne by such Officer as they shall appoint for that purpose." Those who are familiar with the historical summary printed each year in the *College Calendar*, will remember that in 1800 George III had granted a Charter re-establishing the dissolved Company of Surgeons by the name of the Royal College of Surgeons in London, with perpetual succession and a Common Seal, and severing its connexion with the Corporation of the City of London. The centenary of the Royal Charter of Incorporation was celebrated formally in July, 1900, when the President, Sir William MacCormac, gave an address on the progress of surgery from early times, and the rapid advance made in the century that had just closed. On this occasion a large number of honorary fellowships were conferred. Among the lesser provisions of the Charter of 1822 was one permitting the College to provide a proper room, house, or building with suitable conveniences, for the dissection of the bodies of murderers, within half a mile of the usual place of execution, instead of within 400 yards, as formerly. The object of this was perhaps to meet the difficulty caused by the removal from Surgeons' Hall in the Old Bailey (hard by Newgate Prison) to the present site in Lincoln's Inn Fields, at the close of the eighteenth century. The dissection of murderers was abolished by the Anatomy Act of 1832. In 1843 the name of the College was changed by a further Charter to the Royal College of Surgeons of England, and a new class of members, to be called "Fellows," was instituted. The first 300 Fellows were elected in a general body under one diploma on December 11th, and a further election of 242 took place eight months later.

TREATMENT OF LEPROSY IN THE PHILIPPINES.

In a note on leprosy in the island possessions of the United States (November 12th, 1921, p. 808) mention was made of the information on this subject given in the Director's report of the Philippine Health Service in 1919. We have now received the report for 1920. From this we learn that in May of that year a Committee on Leprosy Investigation

¹ *Encyclopaedia of Religion and Ethics*. Edited by James Hastings, with the assistance of John A. Selbie, M.A., D.D., and Louis H. Gray, M.A., Ph.D. Vol. xii. Suffering. Zwingle, Edinburgh: T. and T. Clark; New York: Charles Scribner's Sons, 1921. (Pp. xxiv + 876. 35s. net.)
² See *Journal*, February 7th, 1914 (p. 335), January 9th, 1915 (p. 81), June 17th 1916 (p. 852), and December 11th, 1920 (p. 910).

was appointed to make a thorough study of leprosy in the Philippine Islands, with a view to ascertaining by experiment the most efficacious treatment for the cure of the disease. A group of seventy-six patients was selected from the cases then at San Lazaro Hospital. Patients with active lesions of various types were chosen, but any with evidence of pulmonary, renal, or cardiac disease were rejected; the majority had nodular lesions. The patients were subdivided into five groups, and these were treated respectively with sodium gynocardate "A," sodium gynocardate "S," sodium morrhuate, chaulmoogra emulsion, and Mercado's mixture. The experiments were designed primarily to compare the Rogers treatment (or treatments) with the Mercado method. As a rule, the first three preparations were given intravenously twice a week; the last two were injected intramuscularly once a week. In some cases the subdermal route was employed, and in others two modes of administration were combined. Details of the treatment are given in the Committee's preliminary report. The Mercado mixture is noted as being by far the most painful of all the drugs used, and as giving marked immediate and remote reactions. At the time the work was begun not enough was known of the value of the Holman-Dean chaulmoogra esters to justify their use, but in the light of further information the Committee decided subsequently to select a new group of cases for this treatment. Of the treatments employed up to the time of reporting, sodium gynocardate "A" had given the best results, 86 per cent. of the cases showing some degree of improvement; the figures for sodium morrhuate were 75 per cent. improvement, for Mercado's formula 64 per cent., gynocardate "S" 60 per cent., and chaulmoogra emulsion 38 per cent. The sodium morrhuate and the Mercado mixture seemed to have the most bacteriolytic effect. These results inspired the hope that the new methods of treatment, if used systematically over longer periods, would produce permanent cures in a higher proportion of cases treated than was possible by any previous methods. The Committee accordingly advised that one or more of the chaulmoogra methods be made available for all the segregated lepers in the islands, and that the present investigation be continued on a larger scale, with a view to improving further the methods of treatment. It recommended an appropriation of 600,000 pesos for this purpose, but in view of the depleted state of the insular treasury this was cut down by the Legislature to one-sixth. An account of recent knowledge of the chaulmoogra oil derivatives was given in an article on the treatment of leprosy printed in the BRITISH MEDICAL JOURNAL of November 19th, 1921, p. 851.

PEKING UNION MEDICAL COLLEGE.

ON November 5th last we published an illustrated description of the new Medical College provided in Peking by the China Medical Board of the Rockefeller Foundation, and gave a brief account of the opening ceremonies, which were attended by representatives of many countries, including Japan, Great Britain, Canada, and France, as well as the United States. We have had the opportunity of reading a report made by the secretary of the foundation, Mr. R. Embree, from which we gather that the medical conference was a more serious meeting than we had supposed. On the morning of each of the seven days which the conference lasted two hours were spent in witnessing demonstrations in medicine, surgery, obstetrics, pathology, and various specialties given in six or seven clinics by visiting professors and members of the college faculty alternately. For the next hour one of the visiting scientists gave an address. The members took their revenge in the afternoons, which they spent in sightseeing and junketings. Chinese societies gave luncheons, the foreign legations gave dinners and teas, and the Peking Chamber of Commerce bundled us all off in a flock of automobiles late one afternoon to the summer palace of the late Empress Dowager for a picnic supper and a magic view, by the yellow September

moon, of the royal pleasure grounds among the Western hills." A dinner to faculty, trustees, and delegates "closed Saturday evening in a riot of speech making," but usually the members of the conference were expected to assemble each evening in the auditorium to hear an address on some medical topic of general interest. During all this time the trustees, eschewing pleasure, lived laborious days in the council room of the college, reviewing each item of the budget proposed for the next two years. These discussions were serious, for the expenditure on the buildings, their equipment and supply, has been larger than was originally planned and the costs for the annual maintenance threaten "to become intolerably great." The budgets finally agreed to for the college and hospital for the next three years are slightly below those of similar well-established institutions of high standing in the United States. The classes in Peking are still small and not more than 175 hospital beds are to be used at present. The Foundation recognizes that the college can never hope to train the very large number of medical practitioners needed by the Chinese, but it is intended to set a standard, to train leaders, and to demonstrate what an adequate medical college in China might be. The faculty as it exists to day falls into three groups—first a nucleus of medical men who have served in mission hospitals and schools who were selected from the six or seven hundred medical missionaries in China and further trained with the help of fellowships in England or America before being given positions on the staff; secondly, a group of men who have been brought directly from teaching or research institutions in the West to continue their scientific careers in the new college; and thirdly, Chinese practitioners, who already form a fair proportion of the whole faculty. It is hoped that their number will steadily increase and that their academic and administrative responsibilities will be rapidly extended.

PROSPECTS OF THE PARLIAMENTARY SESSION.

NEITHER the King's Speech at the State opening of Parliament for the new session on February 7th nor the initial debate gave any indication if and when a dissolution is contemplated. But there was no expectation that any hint would be afforded in any case. Finance, Irish legislation, and House of Lords reform were the principal subjects touched upon, but it was noticed that there was no commitment to the introduction of a bill to deal with the reconstitution of the Second Chamber. The word used in the Speech from the Throne was that "proposals" for House of Lords reform would be submitted, thus leaving the course of the Government in this regard undefined. It might conceivably be that only the policy of the Cabinet would be announced. The term might be equally consistent with a resolve to press forward the solution of the problem within the session. A significant declaration in reference to economy was that the retrenchment deemed necessary "must involve hardship to individuals and the postponement of public hopes." A good deal of interest will be aroused in two minor bills which are included in the small programme. The first of these, which is to be introduced immediately by the Minister of Health, Sir Alfred Mond, is to increase the contribution rate and benefit under the National Insurance Act. According to rumour, employers and employed are each to be required to give an extra halfpenny a week in respect of each insured person. The second announcement was that the Government will bring in a Criminal Law Amendment Bill; expectation is that this will be more or less based on the Bishop of London's Bill of last year, which had been modified to meet the recommendations of a Joint Committee. This was shipwrecked in the Commons late in the session. It had the sympathetic support of the Home Secretary on behalf of the Government, but a measure brought forward by a Minister will, of course, be in a much more hopeful position from its very start for getting passed into law.

NINETIETH ANNUAL MEETING of the British Medical Association, GLASGOW, 1922.

GLASGOW TO-DAY.*

TOLBOOTH STEEPLE.

(Photo by Anon, Glasgow.)

FROM the curiously diverse impressions of Glasgow in the minds of Englishmen one thing at least can be deduced with fair certainty. The favourable impressions were those of people who had stayed with friends and been taken about; the unfavourable, of people who had been stranded in hotels. Glasgow does not cater well for strangers. To arrive in Glasgow on a wet Saturday by way of Cowairs or St. Rollox, and spend a lonely week-end in an hotel, is an experience which the native cannot contemplate without a shudder. It would have been more tolerable fifty years ago, when the city was about half its present size and there were charming rural nooks within half an hour's walk from George Square. To-day, with the country smudged or suburbanized for miles around, Glasgow is driven in upon itself for solace. Hence the prodigious outcropping of gorgeous teashops, picture-houses, and dancing palaces. These, however, are mere escapes, of decidedly limited appeal. Their existence may point the need for open spaces and gardens within

the city; for an attractive lay-out of the banks of the Clyde above the harbour; for the dissipation of the smoke-cloud that robs the city's life of light and colour; for the conversion of the depressing and furtive "pub." into a cheerful café; for the removal of ugly posters; and for the building of an opera-house and a repertory theatre. Glasgow's main defect is that she has not yet thoroughly realized her metropolitanism.

The greatness of Glasgow and her glaring defects are explained by her history. Under the shadow of the Cathedral she rose in Celtic times from an obscure village to a market town, which straggled downhill and linked up with a fishing hamlet on the Clyde; with the founding of the University in 1450 she became a social and cultural centre, and the traditions of this period were continued into the mercantile era—commemorated by the Tron Steeples and St. Andrew's Church—when, under the aegis of the "tobacco lords" and the University professors, Glasgow became perhaps the most beautiful city in Britain. Then came the industrial era, the deepening of the Clyde, the working of the coal and iron measures, and the flooding-in of semi-barbarous "labour" from starving Ireland; Glasgow burst her mould, and added to her traditional functions those of a greater Birmingham and a smaller Liverpool. The result was disharmony, a strange mixture of handsomeness and ugliness, of wealth and squalor. Glasgow is still struggling to sort out the mess that culminated about the middle of last century. The struggle is not so much material as psychological. It is the effort of the constructive, intellectual, and civically-minded elements to counter the sordid and illiberal influences that got the upper hand during the height of the manufacturing era.

In the Middle Ages the centre of Glasgow was at the south-west corner of what is now Cathedral Square. By the sixteenth century it had shifted to Glasgow Cross, where the Tolbooth Steeple now stands. A century ago it was some-

* Previous articles, on the City and University of Glasgow, have appeared in the BRITISH MEDICAL JOURNAL of December 3rd, 1921, p. 561, and January 7th, 1922, p. 29.

A smaller outflow finds its way to Dennistoun, a smoke-courged suburb hemmed in by cemeteries, breweries, chemical works, and slums. Then there is a large but more surely percolation to the West End, the region encircling Clingrove Park (Glasgow's finest achievement in town-planting) and the Botanic Gardens. On the South Side one enjoys fresh air, modern improvements, and adjacency to open country, but one is cut off from the life of the city—south of Jamaica Bridge there is not even a passable restaurant—and the majority of the people are "incomers" who have never seen Glasgow Cathedral or read "Senex" or MacGeorge. In the West End one is in close touch with the main life of the city and, through the University and Art Gallery and the orchestral concerts, with the wider world of art and letters; Woodsidehill was the creation of Glasgow's consuls and aristocrats, and Hillhead and Dowanhill have a melancoly that makes up for smokiness. In the great Western Terrace Kelvin-side possesses the finest domestic work of Glasgow's greatest architect, Alexander Thomson ("Greek" Thomson), whose buildings—including St. Vincent Street United Free Church and Queen's Park East United Free Church—the visitor should not miss.

One has accounted only for the bourgeoisie, *grande et petite*. What of the working classes, who form the vast majority of the population, and on whose skill and physical endurance the prosperity of Glasgow is based? Drink, bad housewifery, and recklessly large families have depressed their conditions, and they are probably the worst housed people west of Moscow. The dingy frowziness of the huge barracks in which they are crowded makes the magnificent stone of which Glasgow is built as depressing a medium as English brick. The canyons of Hutchesontown, Camlachie, and Govan are unresponsive even to the crepuscular glamour that poetizes the massive buildings of the city and the West End. That grace of body or mind should be rare in such conditions is little wonder, or that such intellect as manifests itself should run to an arid and resentful doctrinairism. Yet in the fundamental human virtues the Glasgow working classes are rich, and in character and humour second to none among the world's peoples. Their recent intellectual awakening, though it took a crude and even dangerous form, was an earnest of strength and purpose, and of a determination to make the world a little better than they had found it. In this determination, strengthened and guided by school teachers, and by the more humble-minded of the "intellectuals," lies the chief hope of our race. It is probably in those streets which the visitor cannot pass without a sinking of the spirits that the germ of the greater Glasgow of the future could be found.

Glasgow is pre-eminently a "business" city, a fact which is unduly insisted upon by those of its inhabitants who make it an excuse for neglecting its civic and social interests, or

for not devoting their leisure to anything more strenuous than golf or musical comedy. But in the view of those who love their city, industry and business are only means to the great end of making the very most of the rich human material contained in a city where the racial elements of Scotland, mainly Celtic, are uniquely blended.

In a historical perspective the University, even more than the Town House, is the real centre of Glasgow. Glasgow has a great tradition to maintain in philosophy, theology, economics, and, above all, in applied science and in medicine. Her record in art goes back to the days of the Foulis Academy in the middle of the eighteenth century, and the Celtic element manifested itself in the taste and enterprise of buyers like McLellan, in her early appreciation of genuine impressionists like Monticelli, Bondin, and the Marises, and in the

rise of her own Glasgow School, which affected the whole current of British art. In literature she has been less notable, owing to the failure of her publishers and her reading public to realize her new position as the vital centre of Scottish life. A like failure has accounted for her poor record in drama as compared with Dublin, but the defunct Repertory Theatre left an impulse which has been directed into national channels by the Scottish National Theatre Society, recently founded in Glasgow.

With huge stone quarries and much money at her disposal, Glasgow was bound to take a high place architecturally among British cities, and at certain periods her building was directed by a Roman taste for symmetry and magnificence.

The wealth of splendid architecture that she has hidden away in her blanket of smoke, to be blackened by soot and eaten by nitric acid, will only be fully revealed when the citizens of this proud and ancient city have at last made up their minds to follow the example of Pittsburg and consume their smoke in furnaces instead of breathing and swallowing it. Our abiding vision is of a Glasgow familiar with sunshine, a Glasgow in which trees can flourish and white collars last for two days, and in which the standard of public tidiness shall be equal to that of a respectable middle-class home; a Glasgow fit for commercial travellers to live in, and evoking from strangers such praises as were showered by Defoe upon the Glasgow of two centuries ago.

THE arrangements for the special post-graduate courses in surgery under the auspices of the Fellowship of Medicine and Post-Graduate Medical Association, which were noted in our issue of January 21st (p. 110), have now been completed. The course will be held from February 20th to April 1st, 1922, and the syllabus of the course may be had on application to the secretary of the Fellowship of Medicine, 1, Wimpole Street, W.1. The fee for the course is twelve guineas.

UNIVERSITY GRANTS.

THE Vice-Chancellor of the University of London has addressed to the Prime Minister a letter on the same lines as the memorandum presented by the Universities of Leeds, Liverpool, Manchester, Sheffield, Birmingham, and Durham, protesting against the proposal, understood to be seriously entertained, to reduce the grants made through the University Grants Committee to the universities. The general argument is the same as that set out in the note published in our issue of January 14th, p. 71. As in the memorandum of the Northern and Midland universities, it is pointed out, on behalf of the University of London, that though the grants they received the universities were enabled during the war to render to the nation services of vital importance, and that the restoration of the country to full material and intellectual efficiency demands a continued supply by the universities of well equipped men and women able to devote their abilities to the work of education and research, free from the crippling anxieties of inadequate means and uncertain prospects. The Treasury grant helped to make it possible to improve the salaries of teachers, but there is the danger that London will not be able to attract or retain the type of man most suited for university work. Fees for tuition and examination have been raised to a point as high as, perhaps higher than, can be justified if the University of London is to fulfil the primary obligations of its first charter. The Senate of the University therefore urges the Government that it should continue, and at the earliest possible moment increase, the sum spent on activities so vital to the well-being of the country, to the empire, and to mankind, as those carried on by the universities.

GENERAL NURSING COUNCIL FOR ENGLAND AND WALES.

A communication from the Ministry of Health, dated February 4th, 1922, states: A meeting of the General Nursing Council was held on February 3rd, at which Sir Wilmot Herringham presided for the first time since his appointment to succeed Mr. Prestley. All the members who resigned with the late chairman have now withdrawn their resignations, and the Council has resumed its normal activities. In view of various unauthorized and unfounded statements which have been made, Sir Alfred Mond thinks it desirable to state that these resignations had nothing to do either with the question of the syllabus of training or the question of the entry of certificates in the Register. There is, further, no foundation for the suggestion that there has been any controversy between the Council and the Minister. On the contrary the relations between the Council and the Ministry have been uniformly cordial.

MANCHESTER MEDICAL SCHOOL.

The medical school of Manchester is about to celebrate the jubilee of the amalgamation of the Manchester Royal School of Medicine with Owens College, and, at the same time, the 101st anniversary of the recognition of Mr. Jordan's classes in anatomy and surgery at Manchester, as qualifying for the examinations of the Royal College of Surgeons of England. Previous to the recognition of Mr. Jordan's classes no teaching given outside London had been recognized as qualifying for examination purposes by the college.

It is announced that Professor H. B. Dixon, C.B.E., F.R.S., will shortly resign the Sir Samuel Hall Chair of Chemistry at Manchester University; the high standing of the department of chemistry at Manchester has been steadily built up by the long and devoted labours of Professor Dixon, and his impending retirement will break a lengthy association.

LONDON NEUROLOGICAL CLINIC.

The fourth annual dinner of the London Neurological Clinic, established by the Ministry of Pensions, was held at the Imperial Café on January 28th, some fifty to sixty members of the clinic and their friends being present. Sir Maurice Craig and Dr. Henry Head were the guests of the evening, and among others present were Sir John Atkins, Sir Charlton Briscoe, Dr. David Forsyth, and Dr. C. R. A. Thacker. The toast of the Clinic was given by Dr. Danvers Atkinson and acknowledged by the chairman, Dr. H. E. Davison, the medical superintendent of the clinic. Dr. Davison described the great increase in the activities of the institution during the past year; the total number of cases

examined had been over 14,000 and of cases treated over 4,000. Clinics on similar lines had been, or were being, established throughout the country. Dr. W. A. Brend proposed the health of the guests. In reply, Sir Maurice Craig referred to the great development of psychotherapy during and since the war. There had never been a period in the history of psychological medicine when so much advance had been made in the views and theories on this subject. He congratulated the clinic on the excellent work it had been performing, and hoped that it might eventually work on a more comprehensive basis. Dr. Henry Head spoke of his association with the Clinic during the years 1917 and 1918, and expressed his appreciation of the good work that had been done. He referred to the difficulty which arose from the demand of the laity that the physician should be "pontifical," while the present state of our knowledge of psychotherapy often rendered that impossible. The clinic was collecting observations and investigating the causes of neurotic disorders, and it might be accepted that from its efforts good results had accrued and would continue to accrue. A musical entertainment concluded a very enjoyable evening.

Scotland.

LISTER MEMORIAL IN GLASGOW.

THE usual weekly meeting of the Glasgow Medical Lunch Club was held on February 2nd in Ferguson and Forester's Restaurant, when Dr. F. W. Martin presided, and Professor Robert Kennedy was present as the guest of the club. His address took the form of an appeal for the retention of the Lister Ward in the Glasgow Royal Infirmary as a permanent memorial to Lister and the great work he accomplished for surgery and for mankind. It is a matter of common knowledge that it was in the Glasgow Royal Infirmary that Lister first introduced and practised his antiseptic system of surgery. The ward in which he worked still stands, forming the ground floor of the old surgical block not yet demolished, though out of use. In 1912 the infirmary managers decided to retain this original ward as a memorial to Lord Lister, to be utilized as a museum, and following this decision the Lister Memorial Committee proceeded to make a special appeal for funds and for objects of Listerian interest. However, in 1914 the managers rescinded the decision for retention and decided to complete the demolition of the old buildings. During the war the question remained in abeyance, but recently it was raised again at a meeting of the Lister Memorial Committee, when it was determined to approach the board of managers to reconsider its decision to remove the ward. They, however, adhered to their decision for demolition. On December 31st last Mr. A. Ernest Maynard published a letter in the *Glasgow Herald*, in which he reviewed the position and the managers' decision and made a strong protest against the proposed action of the board. This letter was replied to at the New Year's Day meeting in the infirmary by the treasurer, Mr. Timothy Warren, who discussed the question at some length, giving the reasons for the managers' decision. Professor Kennedy proceeded to deal with these reasons seriatim, setting forth strong arguments in favour of the retention of the ward, and hoped that wiser counsels might yet prevail so that such a valuable asset as the original Lister Ward should not be lost, but should remain as a permanent memorial to the man and his epoch-making work. Meantime, it should be noted that, following the rejection by the board of managers of the proposal of the Memorial Committee regarding the ward, it has been decided to use the money already raised to erect a seated statue of Lister adjoining the statue of his colleague Lord Kelvin, in the Kelvingrove Park, in front of the university of which he was so distinguished an ornament. Professor Kennedy made a strong appeal to the members for their support in this important matter. It was unanimously decided, on the motion of the Chairman, to forward to the managers of the Glasgow Royal Infirmary a letter of protest against the proposed demolition of the Lister Ward.

EFFECTS OF THE RELIGIOUS REVIVAL IN N.E. SCOTLAND.

In the annual report of the physician superintendent of the Aberdeen Royal Asylum allusion is made to the recent religious revival in the north-east of Scotland, and the allegation is controverted that the revival was responsible for the mental illness of a number of patients admitted to the

asylum. He states that the revival was confined almost entirely to those engaged in the fishing industry, who are a religious people, but because of the nature of their calling and their consanguinity their emotions are easily aroused. Many reports of a sensational character concerning the effects of the recent revival have been made, but it had been found from personal observation and inquiry that they had been much exaggerated. Since the end of September there had been nine patients admitted from the parishes in which the revival movement had taken place, but this number had frequently been exceeded for a similar period within the last five years. In no case admitted could it be said that the revival was responsible for the mental illness.

Ireland.

ROBERT CAMPBELL MEMORIAL.

SUBSCRIPTIONS to this fund amounting to £859 17s. have already been acknowledged in the JOURNAL (January 15th, 1921). The following additional subscriptions have now been received:—

*H. T. Hardy Green	£	s.	d.
The late John Simpson	2	2	0
R. M. Fraser	3	3	0
R. C. Crawford (Monaghan)	4	0	0
R. Martland Beath	3	3	0
H. E. Rutherford (Larne)	2	2	0
J. Cathcart Eccles	1	1	0
J. Campbell Hall (Monaghan)	2	2	0
J. T. Greery (Coleraine)	5	5	0
Robert Reid	2	2	0
			5	5	0

Total subscriptions received ... 889 1 0

* £1 ls. of this subscription was already acknowledged (January 15th, 1921).

The Robert Campbell Oration.

The committee appointed by the subscribers to the Robert Campbell Memorial Fund have invited Colonel Thomas Sinclair, C.B., in recognition of his eminence as a surgeon, and his long and valued services to the Belfast Medical School, to deliver the first Memorial Oration. The oration will be delivered in the Medical Institute, College Square North, on Thursday, February 16th, at 8 o'clock. The orator will give an account of the life and work of the late Mr. Robert Campbell, followed by an address on the surgery of the blood. The chair will be taken by Sir John Walton Browne, M.D. Members of the profession are cordially invited. Tea will be provided after the meeting by the kindness of the trustees.

Correspondence.

THE RECOGNITION OF AORTIC INCOMPETENCE.

SIR,—In his useful paper on the frequency with which an aortic regurgitant murmur is missed, Dr. Brockbank does not mention the cause which seems to me the most important, a cause to which I drew attention at the meeting of the Association of Physicians in 1920.¹ It is that many aortic regurgitant murmurs are inaudible to the double stethoscope, although distinct to the single wooden stethoscope. I also pointed out that some slight aortic regurgitant murmurs, whilst inaudible to both stethoscopes, are easily heard by the unaided ear laid directly on the chest. I have now in hospital a lad whose diastolic murmur is heard with difficulty with the double stethoscope, a little better with the wooden one, and quite easily by the ear on the chest. In looking for an aortic regurgitant murmur, therefore, all three methods of auscultation should be used. It is unfortunate that the relative merits of different modes of auscultation are still generally unknown. The exclusive use of the double stethoscope at present in vogue is a misfortune for cardiology.—I am, etc.,

Father, Feb. 4th.

W. GORDON.

SIR,—Reading Dr. Brockbank's interesting article on this important disability suggests the question, Was it not Dr. Graham Steele who said that in aortic regurgitation a stethoscope should only be used to clinch the diagnosis?

¹ Practitioner, July, 1920.

Stand the patient so that the light falls obliquely on his neck and casts a slight shadow on the inner side of the sterno-mastoid. Get him to stand still with his chin slightly raised, and note the excessive pulsation of his "swinging carotids." Then slightly abduct the arm of the same side, and slightly flexing and supinating it at the elbow, note the backward and forward writhing of the "locomotor brachial." Then grasping his wrist with your hand of the same side—that is, right with right—so that your palm is in contact with the flexor surface of his wrist, lift his hand above his head so as to accentuate the effects of the rise and fall of blood pressure, and note the distinct tapping against your palm characteristic of the "Corrigan pulse." Then seat the patient facing the light, slightly evert his lower lip, and press a microscope slide against the mucous membrane so as to get a central blanched area, and whilst keeping up a steady pressure, notice how this blanched island waxes and wanes with the ebb and flow of "capillary pulsation."

If these signs are present they suffice to establish the diagnosis of aortic regurgitation, even if at the moment no diastolic murmur can with certainty be heard.

Failure to hear a diastolic murmur may be due to the distraction of extraneous noises, from which handicap even members of medical boards are not immune. It may be due to the presence of numerous riles and rhonchi in the adjacent lungs and the inability of the patient to hold his breath long enough.

It may be due, as Dr. Brockbank points out, to the examiner contenting himself with a casual application of his stethoscope to the so-called aortic area in the second right costal interspace instead of also listening carefully at various points down the left side of the sternum.

And it may also be due to the elusive character of the murmur itself, which in the early stages of this disability may be perfectly obvious one day and impossible to elicit on a subsequent occasion, in either case tempting one to doubt the competence of a previous observer.

Sometimes, unlike a presystolic murmur, it may be heard more easily whilst the patient is standing than when lying on his left side, and the hardest variety of all, in my opinion, is where the semilunar valves close with a clean snap, followed by a short hiss, which is very easily missed. The importance of the early diagnosis of this disability, of course, lies in the fact that in the early stages the exercise tolerance may be so good as apparently to justify the man continuing an occupation which will inevitably accelerate the development of irremediable heart failure.

Although not exhausting the possibilities of this way of examining aortic cases I think I have sufficiently indicated the value of making full use of the unaided senses before having recourse to instrumental aid.

As regards the position of the apex beat, the advice to search outwards well in all heart cases where it cannot be at once definitely located in the normal position is most important. I remember one case where a diffused impulse outside the nipple line resolved itself finally into displacement of the heart due to old lung trouble, the apex beat being finally located near the angle of the left scapula. But as regards the position of the apex beat in aortic cases, as its outward displacement depends on the consequent heart failure, and this again on the degree and duration of the disability, it follows that the object of the examiner should be to establish the existence of incompetence before the displacement outwards has occurred.—I am, etc.,

Manchester, Feb. 6th.

FRANCIS HEATHERLEY.

INFLUENZA.

SIR,—Sir G. Archdall Reid's remarks on past influenza epidemics are interesting and instructive. Having had ample opportunity of seeing many cases in the course of the intensive work of an extensive panel and mining practice, and having observed four cases in my own home, may I supplement them by a brief reference to the present epidemic? Several outstanding types have been noticeable in this area.

First, the ordinary type with pain in head, back, and limbs, and moderate pyrexia. Laryngitis and bronchial catarrh were common accompaniments; epistaxis was not so prominent a symptom as in the last epidemics, but "pink eye" was, I think, as prevalent. On the other hand, cerebral symptoms were very infrequent. Pneumonia supervened in several instances, as many as nine being notified in one day, more particularly among the very young and the old—10 months to 84 years in my practice. A few of these proved fatal, but treatment by means of mustard and flour poultices, stimulants, strychnine, the open window, large quantities of

cold water internally, and cold water sponging, appeared to favour recovery in many instances, one child, aged 14 months, recovering from influenza bronchopneumonia after an illness of three weeks' duration. In the case of adults the compound powder of phenacetin and aspirin, mentioned in the *BRITISH MEDICAL JOURNAL*, yielded good results.

Secondly, there was a gastric form, with, in several instances, what might be termed a pseudo-appendicitis, which quickly resolved, and a few followed by catarrhal jaundice.

Thirdly, there was a type in which there was pharyngitis, usually accompanied by a high temperature, and followed by implication of the middle ear. In the case of my three daughters, one of whom contracted the disease outside this district, it took this form, the temperature at the acute being 101.1, 101, 103.8° F. respectively. One had epistaxis, and in all there followed an irregular temperature and pain in one ear, relieved when perforation and a purulent discharge occurred in two of them; in the case of the third, where the condition was evidently serous, resolution took place. Under treatment by means of cautious syringing with weak lysol, instillation of hydrogen peroxide and absolute alcohol, and nasal irrigation, all made a good recovery. My assistant contracted it locally, and was affected by the gastric type without sequelae.

I had only time to make a hurried examination in my private laboratory of swabs from the throat of one of my daughters, and found no sign of the pneumococcus, but only the *Micrococcus catarrhalis*, many dead cocci being found within the phagocytes after a lapse of a few days, and there was no tendency to chest complications. I learn from an Edinburgh bacteriologist that the pneumococcus appeared to be the prevailing organism in that city.

Whether or not such epidemics will remit for a considerable period is on the knees of the gods, and meanwhile it behoves us to be prepared. As regards prevention, notification is out of the question, otherwise an economy axe of levithian proportions would at once be requisitioned, but possibly an appeal could be made to practitioners to report voluntarily to the medical officer of health early cases of what appears to be the beginning of an epidemic. The Christmas and New Year holidays probably contributed their quota to the rapid spread of the malady, a plentiful supply of carriers and ambulatory cases being quite sufficient to propagate it. Vital statistics regarding the, as it is termed, recent milder epidemic will be found to be disquieting, and it is obviously in the interests of public health to forestall the loss in wages, impairment of health and heavy mortality that ensues.

The closing of schools after the organisms have taken their toll seems to me to be an ineffectual method of dealing with such outbreaks. To prevent recurrence, might not first cases and contacts of all ages be quarantined, for is the disease not more devastating in its effects in this country than plague, cholera, or even small-pox, and is it not of more vital importance to the community than the spread of foot and mouth disease?—I am, etc.,

J. BOYD PRIMMER, M.B., Ch.B., D.P.H.

Cowdenbeath, Fife, Feb. 5th.

Sir,—About three weeks ago I was called to a patient who had a temperature of 101° and some of the initial symptoms of scarlet fever, including redness of the face, excepting round the mouth. The following day the latter had disappeared, and I pronounced the case to be one of influenza. Eight days later a rise of temperature to 100° occurred, and coincidentally the same redness of the face reappeared, again to disappear by the following day. After another eight days' desquamation of both hands, and, to a lesser extent, of the feet, supervened and lasted about five days. A few weeks previously I saw a case, which had been diagnosed as scarlet fever after the preliminary question had been mooted whether it might not be scarlet fever, in which desquamation of the hands had also taken place; it was very difficult to give a verdict as to which of the two it had been. In view of the first case mentioned above, it being obvious that it could not have been scarlet fever with two rashes at an interval of a week, it appears that some of the present cases of influenza very closely resemble scarlet fever. A colleague of mine to whom I spoke about the matter informs me that he has seen exactly the same thing occur in cases which were undoubtedly influenza.—I am, etc.,

London, W., Feb. 6th.

EDGAR F. CYRIAX.

PREVENTION OF VENEREAL DISEASE.

Sir,—An address on the failure of self-disinfection, which was delivered on November 14th last by Lord Gorell in his capacity as President of the National Council for Combating Venereal Diseases, is now on sale. Venereal disease has spread so vastly in recent years, and is now so great an evil, and Lord Gorell's address contains so many misstatements and misinterpretations of fact, that his essay ought not to pass without protest. All the statements we are about to make have long been known to Lord Gorell and his colleagues. None of them have been disputed, or are likely to be disputed. They are founded on evidence, all of which is accessible, and much of which may be found in official publications.

In 1906 Metchnikoff discovered a method of aborting syphilis which was quickly adopted by most of the armies of the Continent and the British navy. In 1913 a Royal Commission was appointed to consider the means by which the effects of venereal disease "can be alleviated or prevented." Some of the medical members wished to cite Metchnikoff, but were told that the feeling among the clerical and female members was such that any attempt to discuss prevention would wreck the Commission. Ultimately it advised the Government to increase the facilities for treating the infected, and for exhorting the community to chastity. But never yet in the history of medicine has the prevalence of any infectious disease been reduced by mere treatment. In addition the Commission warmly commended to the Government for its future guidance the newly formed National Council for Combating Venereal Diseases. In other words, it warmly commended itself, for the Chairman of the Commission became the President of the Council, and was accompanied to the directorate of the latter by about half his colleagues. The advice was accepted by the Government. The N.C.C.V.D. became very influential and ultimately was entrusted with considerable sums of public money, which it expends mainly in advertisements and on lecturers who expound the horrors of disease but are forbidden to mention prevention—that is, sanitation.

In 1916, when the nation was in peril, when trained soldiers were flowing by tens of thousands into the venereal hospitals, when the Colonial authorities were threatening to withdraw their forces unless better protected from sex diseases, when in every Dominion a disloyal faction clamoured against sending "our clean lads to the British cesspool," the authorities proposed to introduce self-disinfection into the army by means of "packets," somewhat after the navy fashion. But "influential people," members and supporters of the Council, intervened, and ultimately the authorities, fearing agitation, established instead "venereal ablation rooms" for what was described as "early treatment"—an inaccurate and stupid description, for the authorities and the influential people knew quite well that the attempt was to prevent disease, and the soldiers, as long as they escaped the consequences, cared not a jot whether it was by way of prevention or cure. But prevention suggests quick, and treatment slow, action; and it seems that a certain number of soldiers, deceived by the description, did actually use the disinfectants stored in the ablation rooms—permanganate of potash in pails and calomel cream in pots—for treatment after disease had declared itself. Moreover, the scheme was defective in that the first principle of efficient disinfection, timely action, was ignored, and in that men in isolated posts and on leave received no protection. Again, since the authorities feared that they might be charged with encouraging vice even such instruction as was given to the men was extremely vague and scrappy. At this time the infections among leave men in London alone were calculated at 1,000 a week. However, even delayed disinfection, no matter how inefficient, partial, and vilely taught, is better than none, and the army war rate of infection in the United Kingdom fell in *war time* from the lowest *peace* rate of 59 to 38.

But some medical officers, more concerned with the health of their charges than of possible censure, disregarded the official instructions—in the navy and in the army—before, during and after the war, in India, Egypt, Iraq and France, the Cape, and the West Indies; and advised their men—merely advised, for they had no disciplinary power and were themselves offenders—to carry disinfectants if likely to get into danger. In every such case the men were told that the disinfectants were *merely* disinfectants, useless for cure, and that they must be used with all possible speed after danger had been incurred. Among the soldiers so instructed disease invariably fell to the vanishing point; none used disinfectants for treatment; and very few, if any, returned

infected from leave. As Lord Gorell notes: "A disinfectant does not disinfect in the hands of an unintelligent person any more than a typewriter types in the paws of a baboon." But it does disinfect, as massive evidence indicates, in the hands of an intelligent person, and the question is, Who made the British soldier unintelligent in this matter? Lord Gorell quotes figures from "a prominent venereal disease clinic" about men who used the "particular disinfectants" recommended by the Society for the Prevention of Venereal Disease. But did these men use the disinfectants as the society recommends? Lord Gorell is merely describing the results of "early treatment" as taught during the war. His statement that "if we examine the figures and experiences with which they deal we find in practically every case they come down to the success achieved by Sir Archdall Reid . . . dealing with army units on a small scale and carrying on personal and individual instruction," is merely nonsensical. Reid gave personal, but not individual, instruction; he had 2,000 men in charge; 20,000 passed through his hands; he was not the first, nor the last, to prevent disease; he did not work on the most extensive scale, nor under the most difficult conditions, nor was he the most successful worker. His experiences are well known partly because, being a civilian, careless of official censure, he published an account of them, and partly because it has been the policy of the National Council to represent his success as the only one. If Lord Gorell cares to challenge us we shall be happy to supply details; but he may find them set out with some fullness in Reid's own book, with which, doubtless, he is familiar.

Early in 1918, when the German offensive was impending and the British army depleted, the authorities became aware of the success which had attended the teaching of quick disinfection and ordered its extension throughout the army. It was earnestly impressed on them that since disinfectants were already present in abundance with every unit, not a shilling's expense nor a moment's delay was necessary. All that was necessary was an order to medical officers to instruct their men in unequivocal language. Nevertheless, delay occurred, and it was discovered that, following the advice of an "expert," the authorities were awaiting the manufacture and delivery of 4,000,000 bottles and 1,500,000 tubes. Protests proved unavailing, and the suggestive packet system was thus introduced, against the advice of those who are now accused of advocating it, by the very people who make that accusation. The delay gave "influential people" their opportunity, and the minor officials to whom the matter had been entrusted proved obliging. The packets, when at last delivered to medical officers, were accompanied by instructions that they were to be used for early treatment. When a medical officer stated that he intended to teach quick disinfection he was told that such a procedure would arouse the wrath of the Church. Conceive the imbecility of the whole procedure. At vast delay and expense disinfectants were transferred from pails and pots to bottles and tubes—nothing more. Vehement protests and prophecies of certain failure were again made, and again proved unavailing. Probably the protests never passed beyond the hands of the minor officials. The predictions were fully realized. The failure was complete.

Nevertheless, as is the way of successful procedures, the practice of quick disinfection continued to spread. In 1919 it was quietly adopted for the whole of the Portsmouth area—almost all Hampshire and Dorsetshire. Throughout this great area, in which were many camps and barracks, disease, as usual, fell to the vanishing point. But in it were large bodies of Americans, Colonials, and R.A.F. who did not belong to the British army, were not instructed, and were highly infected. Into it also came infected drafts from other areas, and on demobilization vast numbers of highly infected troops from overseas. The military authorities, therefore, kept a careful count, which differentiated locally acquired from imported disease. These figures are still available.

In 1919 an Interdepartmental Committee, composed of governmental servants and denounced from its inception as liable to be dominated by influential people, was appointed by the Ministry of Health to consider, among other problems of demobilization, that of venereal disease. Suitable statistics were furnished to it by the obliging officials. Obviously, the business of this Committee should have been to ascertain how it happened that while, in many countries, on many occasions, under many conditions, disease had been reduced to the vanishing point by many medical officers, it had continued to rage among neighbouring bodies of men, and how it happened that in these fortunate areas men did

not return infected from leave, or use disinfectants for treatment. The evidence was experimental: for each attempt to prevent disease by careful teaching was an experiment: and the peculiarity of experiment is that a single success outweighs a thousand failures. In the face of success, failure indicates only faulty technique. But these considerations do not seem to have influenced the Committee. Instead it took the statistics of disease as a whole, lumped them together, assumed in spite of abundant evidence easily accessible in official records, that quick disinfection had been universally taught, announced that self-disinfection had failed, and, of all things in the world, called attention to the "neglected moral factor." Heaven knows what happened in the privacy of the Committee, but only the Chairman, Lord Astor, signed the report. He has since declared that the Committee was quite impartial and published the statistics as received. But did it publish all the statistics? Did it even ask for them? Why, for instance, was Sir James Barrett's magnificent success, achieved on a grand scale under the most difficult conditions in Egypt among the Australians, not so much as hinted at?

The scandal created by this report led immediately to the foundation of the Society for the Prevention of Venereal Disease. On December 10th, 1919, the president, Lord Willoughby de Broke, asked in the House of Lords for information about the Portsmouth area. He was informed by the late Lord Sandhurst, the then representative of the Ministry of Health, that venereal disease, which formerly had been twice as prevalent in the Portsmouth area than in the rest of the country, was in 1919 two and a half times more prevalent. This statement was immediately stigmatized in the public press by one of us as "monstrously inaccurate." Thereupon the Ministry of Health, in February, 1920, published a White Paper in which it was admitted that a great mistake had been made. It seems that the ingenious statistician of the Ministry had taken the diseases in the whole area—in the British army and out of it, imported and locally acquired—and attributed it to the relatively small garrison of Portsmouth town. Actually while disease in the rest of the country had risen from 38 to 64, that in the Portsmouth town had fallen from 92 to 54, and in the area to 47. The ingenious statistician, who is the same person as furnished the Interdepartmental Committee and Lord Sandhurst with their figures, who to this day supplies the N.C.C.V.D. with its statistics, and who we understand will presently publish a characteristic statement, does not attempt to explain the fall of the disease rate in Portsmouth town and area; but he does try to explain why their rates did not rise in 1919 in correspondence with that in the rest of the country. This is his explanation: that the Portsmouth town and area had not a port of entry for overseas troops. But, as was certainly known to the statistician, Southampton, the largest port of all, in peace a part of the area, in war detached merely for administrative purposes, is a mere enclave in the area. Not a man passed out of it by land except into the area; and in 1919 the whole of the latter, including Portsmouth town, was flooded with overseas troops and its hospitals swamped with their diseases. Almost the whole of the 54 and 47 was due to imported disease, the infections acquired by the instructed troops being almost negligible. But the real facts about venereal disease in 1919 have not been made public. There is reason to believe that the figure 64 is quite inadequate. It was stated in Parliament that it was impossible to be precise. But, as we see, a regard for precision has not hitherto characterized the authorities directly concerned. Doubtless many thousands of men were demobilized while still infected, but this has always happened. Previously the authorities had relied on a comparison between the troops with the colours with those in hospital, and there was nothing to prevent the employment of the same method in 1919. But it is probable that the results were too horrifying, and, therefore, damning.

Lord Gorell insists that it would be impossible to instruct civilians. Examine, then, a series of undisputed facts. In 1885 the venereal rate of the army in the United Kingdom was 275. It decreased steadily and in 1913 was 50. Presumably, since soldiers infect and are infected by civilians, the latter shared in the decline, which must have had some effective cause. The Interdepartmental Committee attributed it to improved facilities for recreation, and the like. But can anyone in his senses believe that the young men of to-day are five times more moral than their fathers because of such things as football and light literature? The only alternative is that the decline was consequent on improved

sanitation. As far back as the eighties a knowledge of anti-septics had reached the public; disinfectants were present in many homes; men used them after dangerous intercourse, and some prostitutes offered them to their customers. The truth of this explanation (that disinfectants disinfect) was strikingly confirmed during the war. In 1916 ablution rooms for self-disinfection were established, and the N.C.C.V.D., assisted by public money, began an intensive campaign of exhortation and exposition of the horrors of disease—the former an appeal to morality, the latter to expediency. The military rate fell at once to 33; but both disease and immorality spread enormously among civilians, the increase being especially marked among women; for three out of four soldiers were now infected by amateurs. What explanation of all this is conceivable except (1) that self-disinfection succeeded (in a measure) among soldiers, (2) that exhortation failed among civilians, and (3) that the appeal to expediency made men, not chaste, but merely cautious, causing them to avoid the dangerous prostitute for the pursuit and seduction of the wretched amateur?

To sum up: Two methods of preventing venereal disease by self-disinfection have been practised in the army—unequivocal teaching of immediate disinfection, and equivocal teaching of delayed disinfection (that is, "early treatment"). Whenever and wherever the former has been employed disease has been reduced to the vanishing point; whenever and wherever the latter has been practised there has been relative failure; whenever and wherever this failure has occurred it has always been attributed to quick disinfection. Notwithstanding all its protests the N.C.C.V.D., except perhaps in the earliest months of its career, has never opposed self-disinfection in the army. It has opposed only the teaching of efficient disinfection. In 1916, when some form of prevention became imperative, it caused the substitution of venereal rooms for packets which, though suggestive, and therefore objectionable, could be used for quick disinfection. But in 1918, when it was proposed to discard the rooms in favour of simple teaching, people who are to-day prominent members of the Council first forced packets on the army; next, at the direct instigation of the Council, gave instructions for them to be used for early treatment; and lastly proclaimed the unhappy results of the latter as those of quick disinfection. This astonishingly fallacious reasoning has been exposed on many occasions and never been defended or denied. Nevertheless to this day the Council exploits it, and Lord Gorell is plaintive because his association is called a "fake society." The N.C.C.V.D. can easily prove its bona fides by meeting the charges made against it, or, better still, by joining the S.P.V.D. in a demand for a public inquiry, conducted not by officials but by men of independent standing.—We are, etc.,

H. BRIAN DUNN,
G. ARCHDALE REID.

February 6th.

CERTAIN ASPECTS OF PAIN.

SIR,—At the Edinburgh meeting of the British Association for the Advancement of Science we brought forward experimental evidence that pain in the upper abdomen was associated with contractions of the viscera. We were informed at the time that the workers at the St. Andrews Institute for Clinical Research had reached a similar conclusion, and we have read with interest the fuller statement which has appeared in Sir James Mackenzie's letter (January 28th, p. 161.) It cannot be said that such a result is very unexpected, as it is now some ten years since Cannon and Washburn's observations on the painful hunger contractions of the empty stomach were published, and these have been confirmed.

The subject is, however, less straightforward than would appear at first sight, because we have found that contractions do not invariably cause pain, and they may abolish it when it is present. We are at the present time investigating the matter by the experimental method, combined with clinical observation. Without the former we do not think that the question will be satisfactorily elucidated.—We are, etc.,

W. W. PAYNE,
E. P. PACTOX.

Guy's Hospital, S.E., Feb. 2nd.

ALPINE TREATMENT OF TUBERCULOSIS.

SIR,—The seven years' reign of the passport tyrants in all Foreign Offices and Consulates and other interferences with free international travel resulting from the war have had a disastrous effect upon the treatment of tuberculosis.

The English fled from Davos and Arosa before the invasion of German lung cases during the war. The British Davos

Sanatorium, built under the patronage and name of Queen Alexandra, after vain appeals in your columns by the late Lord Balfour of Buthleigh and others, has recently been sold by its committee to the Cantons of Schaffhausen and Thurgau. In spite of the efforts of Lord Balfour, Dr. Mitchell Bruce, Sir William Wilcox, and several others who tried in vain to save it for the nation, this institution, which the Queen Mother had fostered and which had been a great blessing to so many English patients of moderate means, has been disposed of at a very low figure to the Swiss authorities.

During the war consumptive sanatoriums sprang up in England in all directions to meet urgent military necessities, and the treatment of tuberculosis in this damp and sunless climate grew rapidly.

I believe that I was the first English writer to call attention to the remarkable plateau of Montana. This place with Villars sur Ollon and Ley-in on the north side of the Rhone Valley furnish unique conditions for the treatment of this terrible disease. Some very influential representatives of the medical profession, including Dr. Mitchell Bruce, Sir Humphry Rolleston, Sir William Wilcox, Sir John Broadbent, Sir Charlton Briscoe, and others whose names are known throughout the medical world, visited Switzerland last summer as guests of the Swiss Government to inspect the Swiss health resorts. As a result of these visits several articles appeared in the *Lancet*, *British Medical Journal*, and the *Journal of Tuberculosis*, in which the writers testified that the climate and other conditions of the north side of the Rhone Valley are of great value in dealing with the disease.

From time immemorial the dryness of the climate in the Valais on the north side of the Rhone has been so great that former generations have constructed what would be called in India huge "tanks" or small lakes for the irrigation of the vineyards which stretch along the whole of that side of the Valais. The long duration of sun produces wines almost as strong as the Italian wines. On the shortest day in winter these alpine slopes enjoy two hours more sunshine than the alpine lung resorts in German Switzerland.

I venture to suggest in your columns that the funds from the sale of the Queen Alexandra Sanatorium now in the hands of the committee might well be supplemented by some generous donor or donors for the purpose of re-establishing in French Switzerland the work carried on in Queen Alexandra's name with such benefit to our countrymen.

I am supported by the best medical opinion in saying that recoveries are more probable and more rapid in an institution situated in such a district as I have described than can be hoped for, under any circumstances, within the range of the British Isles.—I am, etc.,

House of Commons, Feb. 6th.

MARTIN CONWAY.

MENTAL HOSPITALS.

SIR,—I am much interested in Dr. Edwin Goodall's letter of February 4th, and cordially agree with him in his desire that early mental treatment should be available in "conjunction with, and as part of, general hospitals" with medical schools attached.

I presume that when Dr. Goodall uses the expression "free from any connexion with lunacy laws" he means free from certification. Yet if he wishes the indoor clinics to be under the Board of Control, surely it is the same thing as being under lunacy administration. There can be no more reason for placing uncertifiable cases under the board than for submitting general hospitals to the same control.

Surely Dr. Goodall is in error in implying that any penalty is incurred in treating uncertifiable cases on hospital lines where there is no detention. I looked, but in vain, for an explanation of the surprising fact that, in view of repeated extension in asylum accommodation by building new asylums, there should be at the present time 18,000 vacancies.

The whole atmosphere must be cleared and daylight let into the dark corners of the whole asylum system. As so admirably expressed in your leader to-day, "it now remains to arouse the interest of the public, to whom the whole question of mental disorder is one of vital concern."

The problem of mental disorder is not a simple one. It cannot be dealt with solely from a medical or from a legal aspect. It is a human problem. Every branch of the community is involved, and therefore ought to have a voice in the matter. All kinds of social questions need handling before there can be any hope of arriving at a satisfactory solution.—

I am, etc.,

London, W., Feb. 4th.

OCTAVIA LEWIS.

HOSPITALS IN THE TERRITORIAL FORCE.

SIR,—“Late Captain à la Suite” and I agree on the main point, that the present system of the Territorial Force hospitals needs amendment, and it appears that the War Office thinks so too. But whether they will reform the organization on “Late Captain’s” suggestions remains to be seen.

I see no reason for detailing in public the shortcomings of the Territorial Force hospitals. “Late Captain” and I agree that the system did not work satisfactorily. There has been too much newspaper criticism on both persons and military matters already, and I will not be a party to add more dirty linen for public washing.

I regret “Late Captain” thinks I wrote in anger. There was nothing to be angry about. I intended to say that I thought the views expressed by your correspondent were founded on a want of knowledge and that his remedies were unworkable.—I am, etc.,

BERTRAM M. H. ROGERS.

Bristol, Feb. 2nd.

RUBBER DENTURES.

SIR,—In the BRITISH MEDICAL JOURNAL of January 28th Mr. Spencer draws attention to the fact that some patients who wear rubber dentures suffer from persistent irritation of the tongue in consequence; whereas, removal of the dentures, or their replacement by metal ones, causes its disappearance.

In the early seventies there was, among dentists, considerable controversy about this matter, and in 1876 the late Professor Atfield, F.R.S., at that time Professor of Chemistry to the Pharmaceutical Society of Great Britain, at the request of Messrs. Ash and Son, the well known dental manufacturers, undertook exhaustive chemical tests, which led him to the opinion that rubber was quite suitable for prosthetic work in the mouth, in that it was a perfectly innocuous substance.

A committee of the Odontological Society, who at that time were making their own investigations, received Professor Atfield’s report from Messrs. Ash, who were largely responsible for the manufacture of dental rubbers. To this report they had little to add. They came to the unanimous conclusion that rubber (red or black) may exercise some irritating effects upon the tissues with which it is in immediate contact, but that there is not the smallest evidence that these are due to its chemical composition.

As far as I am aware, no other scientific report on this question has been published, as the findings of that committee have never seriously been disputed by the dental profession.

The fact that rubber is now so extensively used in prosthetic dentistry, I think, supports Professor Atfield’s views. For his report see page 208, *Transactions Odontological Society*, 1876-77.—I am, etc.,

Watford, Feb. 3rd.

SIDNEY FISK.

SARCOMA OF BONE.

SIR,—I beg leave to correct the brief summary in the JOURNAL of February 4th, p. 188, of a paper read by me at a recent meeting of the Leeds Division of the British Medical Association.

The paper dealt with pathological aspects of sarcoma of bone, and included a comparison of the highly malignant osteosarcoma with the lowly malignant myeloid sarcoma. Evidence was adduced to show that the latter was, however, undoubtedly neoplastic in nature, and not a haemorrhagic osteomyelitis, as suggested by some recent American writers. It was pointed out that, unless local removal was done thoroughly, there was considerable risk of recurrence *in situ*, and that curettage especially must be done in a very careful and thorough manner.—I am, etc.,

University of Leeds, Feb. 4th.

M. J. STEWART.

MULTIPLE TOOTH EXTRACTION.

SIR,—Mr. Devison Pedley (January 14th, p. 80) makes a very interesting statement, its very simplicity adding value to its truth. He says: “It is rarely necessary to remove all teeth when affected by pyorrhoea alveolaris, and any inflammatory condition of the gums may be, and often is, mistaken for this somewhat intractable, but by no means incurable, disorder.” “That greater care should be exercised by medical practitioners before pronouncing definite decisions is easily proved.”

The frequency with which patients are advised to sacrifice the whole of their teeth without positive proof of the necessity of so doing is really astounding. During the past few years I have had a very large number of cases of septic conditions

of the gums referred to me for radiographic examination, and it is surprising how large a percentage of these patients are found not to be suffering from pyorrhoea alveolaris at all. In the larger number the trouble has arisen from peri-apical sepsis, the pus from which has found its way to the gingival margin and burrowed along in either direction and oozed from between the teeth.

The identification of the foci of sepsis will indicate a local operation involving probably the loss of one or two teeth only. The medical practitioner is undoubtedly awakening to the wisdom of ascertaining the true condition before operation, but he is not yet fully awake.—I am, etc.,

London, W., Jan. 27th.

CHRISTOPHER KEMPSTER.

BIOLOGICAL EFFECTS OF X RAYS.

SIR,—It appears to me to be a great pity that Dr. Mottram (p. 164) should have been so hasty in his criticisms of Dr. W. J. Turrell’s theory of the action of x rays. He speaks scathingly of a “mythical toxin.” It is evident that Dr. Mottram has not had the advantages that I have enjoyed of having many talks with Dr. Turrell on the subject, and of reading that part of his MS. in which he deals at length with his theory and its basis. As I understand that Dr. Turrell’s book will be published this week, Dr. Mottram will have an opportunity of a closer study of this very interesting problem, after which he may, or may not, feel inclined to enter into a controversy with Dr. Turrell himself. It would be presumption on my part to take up the cudgels on Dr. Turrell’s behalf.—I am, etc.,

J. CURTIS WEBB,

Honorary Radiologist, Gloucester Royal Infirmary.

Cheltenham, Jan. 31st.

Obituary.

WILLIAM CRAIG, M.D., F.R.C.S., F.R.S. EDIN.,

Lecturer on Materia Medica, Surgeons’ Hall, Edinburgh.

THE death, on February 3rd, of Dr. William Craig, in his 90th year, has divided another of the comparatively few remaining links uniting the medical Edinburgh of the twentieth century with that of the sixties and seventies of the nineteenth. The son of a farmer of Lanarkshire, he was born on March 28th, 1832, received his school education in Ayrshire, and took out arts classes in Glasgow University. He graduated at Edinburgh in 1868 as M.B., C.M., and L.M.; he passed on to the M.D. degree in 1870, and soon thereafter began his life-work of teaching materia medica and therapeutics in Surgeons’ Hall School of Medicine, a task which he did not relinquish till two or three years ago. During these many years he never lacked students, and he taught a rather uninteresting subject with such practical good sense and so clear an understanding of the undergraduate’s needs that he retained marked popularity, and was held in kindly reverence as the father of the extra-mural school. He was also one of the small group of teachers who formed the board of studies of the Medical College for Women at its inception in 1890, and he remained lecturer to the women students till their entrance within the walls of the University in 1916. He had become L.R.C.S. Edin. in 1868, and proceeded to the Fellowship in 1874; he was also a Fellow of the Royal Society of Edinburgh and of several medical societies, with two or three of which his connexion was long and most active. For instance, he joined the Obstetrical Society in 1870, and from 1875 to 1910 he was its treasurer; he edited the *Transactions* of the Medico-Chirurgical Society from 1882 to 1909; and he was president of the Botanical Society.

For many years Dr. Craig was an examiner in materia medica for the College of Surgeons, and for a time he performed the same duty for his Alma Mater. He was on the medical staff of the New Town Dispensary; and, last but not least, he conducted a large private practice in the Bruntsfield district of Edinburgh, where his home was situated. He leaves two sons, one of whom is a medical practitioner in Edinburgh. All his life long he enjoyed the best of health, and until within two or three days of his death he had scarcely ever had to keep his bed. He was, as may be expected, fond of an outdoor life, and was a capital shot. He was an elder, first in the United Presbyterian and then in the United Free Church of Scotland. His pen was not inactive; for many years he contributed the Monthly Periscope of Materia Medica and Therapeutics to the *Edinburgh Medical Journal*.

and to the *Scottish Medical and Surgical Journal*; he edited the third edition of Milne's *Materia Medica* and of Milne's *Pharmacological Tables*; he was the author of a *Manual of Materia Medica* and of *Pharmacological Tables*, and he made contributions to various journals on "Changed Aloin," on "Jaborandi," on the "External Uses of Hydrate of Chloral," and other matters.

We have received the following appreciation, signed "F. M. C.":

In his 93th year, after a short illness, Dr. William Craig, the oldest medical practitioner in Edinburgh, has passed away, leaving behind him kindly memories of pleasant associations and the record of a helpful, active life. He was indeed a practical example of what loyalty and devotion to a profession can accomplish, for, while busily engaged in practice, he yet found time to support the leading medical and scientific societies, and considered it a duty to do his utmost by laying his capable business-like methods at their service in most inspiring fashion. A regular attendant at their meetings, he contributed interesting articles on various subjects, chiefly pharmacological, and exhibited pathological specimens. He occupied for many years the position of treasurer to the Edinburgh Medico-Chirurgical Society, and also signalized his duties as editor of its *Transactions* by compiling, in conjunction with his son, Dr. Peter Craig, a valuable analytic index of the first twenty volumes (new series). His services were also greatly in request in the Royal College of Surgeons and in the Obstetrical Society of Edinburgh, in addition to finding outlet elsewhere. Dr. Craig was an ardent botanist, and in his student days won the gold medal for his herbarium. A prominent member of the Botanical Society, he was also associated with the Botanical Club and the Scottish Alpine Club, where he was equally zealous and foremost. He spent many a happy day in mountain and glen, always welcome and in no small measure enhancing the enjoyment of every excursion. Upright, earnest, and genial, his interests in the old activities never waned, nor will his personality and kindly smile fade from the recollections of his numerous circle of friends.

We regret to record the death of Dr. JOHN FRANCIS PRIDIE, which took place suddenly at Southport, on January 27th. Born in Edinburgh, Dr. Pridie received his medical education at the university there, graduating M.B., C.M. in 1887. He afterwards studied at Göttingen, and held resident appointments at Glasgow Royal Infirmary, Edinburgh Royal Asylum, and Southport Infirmary. He went into practice at Chingford, near London, where he remained for thirteen years, but he returned to Southport seventeen years ago, entering into partnership with Dr. Barwise. In 1911 he became a member of the Town Council, on which he did much useful work, particularly in connexion with public health, and for the past year or two he had been vice-chairman of the health committee. He was much interested in medical affairs, and was president of the Southport Division of the British Medical Association, chairman of the Local Medical and Panel Committee, and vice chairman of Southport Medical Society. Dr. Pridie led a strenuous life, for, in addition to the claims of a large general practice, he devoted much attention to his municipal work. He leaves a widow and two sons, the elder of whom won the D.S.O. in the war, and has just passed his final examination in medicine.

Universities and Colleges.

UNIVERSITY OF OXFORD.

In a congregation held on Thursday, January 26th, the following degree was conferred:

BACHELOR OF MEDICINE (B.M., B.Ch.)—Gordon Cranstoun, Oriel College.

Science Departments.—In a congregation held on Tuesday, January 31st, a statute was introduced to modify the present method of administration of the natural science departments. The statute, which it is understood did not meet with the approval of the staffs of the natural science departments, was opposed. On a division, the preamble of the proposed statute was lost by 65 votes to 62. It is understood that a new statute will be brought in at an early date.

Hadjilope Travelling Fellowship.—An ship of the annual value of £200, and to be held during the present term at the meeting on Tuesday, February 21st, have passed all the examinations for the degree of Bachelor of Arts and for

Medicine. They must not have exceeded four years from the time of passing the last examination required for the degree of Bachelor of Medicine. The successful candidate must before election declare that he intends to devote himself during the period of his tenure of the Fellowship to the study of medical science and to travel abroad with a view to that study. The Regius Professor of Medicine and the Examiners, two months before the expiration of the second year after the election of each Fellow, present a report on the work done by him to the Electors, who may, if they think the report unsatisfactory, declare the Fellowship forfeited. The examination will occupy four days. Papers will be

The Services.

REVIVAL OF THE MILITIA.

IN April, 1908, a Special Reserve of Officers was created by Royal Warrant and officers of the Militia were given commissions therein. A new Royal Warrant, dated January 27th, 1922, revives the "honourable designation of Militia for this branch of Our Service." Accordingly, this branch of the Reserve of Officers (with one exception in the case of Household troops) becomes part of the Militia, and officers who were serving therein on October 1st, 1921, are deemed officers of the Militia as from that date. An Army Council's instruction on the new Warrant states that the conditions of service and of remuneration of the Militia are under consideration. When they are published officers of the Special Reserve of Officers will be given the option of continuing to serve under those conditions or of resigning their commissions. In the meantime they will be subject to the existing regulations.

Medical News.

MR. PERCY SARGENT, C.M.G., D.S.O., has been appointed honorary consultant surgeon to the Ministry of Pensions.

A COURSE of eleven clinical lectures on the diagnosis and treatment of cancer will be given at the Cancer Hospital, Fulham Road, S.W., on Tuesdays and Fridays, at 4 p.m., commencing February 21st, when Sir Charles Ryall will speak on cancer of the tongue. The lecture on Friday, February 24th, will be given by Mr. W. E. Miles and will deal with cancer of the rectum. Medical practitioners are cordially invited to attend.

THE anniversary dinner of the Medical Society of London will be held at the Wharfedale Rooms, Hotel Great Central, on Wednesday, March 8th, at 7.30 o'clock.

MR. E. B. TURNER, F.R.C.S., will lecture on "Sex relationships," as discussed at the recent Church Congress, on Thursday, February 16th, at 8 p.m., at the Essex Hall, D-sec Street, Strand. The meeting has been arranged by the Society for Constructive Birth Control and Racial Progress.

THE estate of the late Sir G. Sims Woodhead, who died on December 29th, has been sworn of the gross value of £5,579.

IN connexion with Professor Henri Hartmann's lecture before the Medical Society of London on Monday next, February 13th, at 8.30 p.m., an exhibition of specimens illustrating inflammatory strictures of the rectum is being arranged, and will be on view in the Society's rooms on Monday afternoon and evening and on Tuesday morning.

A COURSE of five lectures on recent researches on the accessory food factors (vitamins) will be given by Dr. S. S. Zilva at the Battersea Polytechnic on Thursdays at 5.45 p.m., beginning on March 2nd.

A MEETING of the Medical Officers of Schools Association will be held at the house of the Medical Society of London, Chandos Street, W.1., on Wednesday, February 22nd, when Mr. George H. Widdows, F.R.I.B.A., architect and surveyor to the Derbyshire Education Committee, will open a discussion on the ideal class room.

AT the meeting of the West Kent Medico-Chirurgical Society to be held in the Board-room of the Miller General Hospital, Greenwich, to-day (Friday), at 8.45 p.m., Dr. C. O. Hawthorne will deliver an address, entitled "Some Pulse Tracings and their Meanings."

THE number of deaths from influenza during the week ending February 4th shows, as was expected, an appreciable decrease. In the 105 great towns of England and Wales the figures were 1,144 against 1,450 in the previous week; in the 96 great towns there were 1,121 deaths from the disease as against 1,420; in London the figures were 191 against 320. In certain South Wales towns there were considerable increases, and also in certain northern towns, including Liverpool, Wallasey, Leeds, York, and West Hartlepool, whilst in other places the numbers declined. The figures for Edinburgh and Glasgow were also below those for the previous week.

At the annual dinner of the Incorporated Vermin Repression Society, with Dr. Nathan Raw, M.P., in the chair, Colonel S. J. M. Auld suggested that the administration of the Rats and Mice Destruction Act (1919) should be taken out of the hands of the Ministry of Agriculture and handed over to the Ministry of Health. They did not ask for the prosecution of the small householder, who was really a sufferer from the overflow of vermin from congested centres, but they wanted to get at the headquarters of the rat, which was in wharves, warehouses, ships, and agricultural buildings, and they called for more prosecutions of the chief offenders. Mr. Alfred E. Moore (honorary director of the society) said that there had been few statutes so badly administered as the Rats Act; the Ministry of Agriculture was no friend of the Act, and the four men responsible for enforcing it upon the local authorities had been dismissed. "Rat weeks" in London were useless, because the rat simply used the sewers as highways to seek temporary sanctuaries where they were not being persecuted. Mr. Mark Hovell, Dr. A. Balfour, and Professor F. Hobday were among others who spoke at the dinner.

THE Umberto I Prize of the Rizzoli Orthopaedic Institute, Bologna, has been awarded to Dr. Murk Jansen of Leyden in recognition of the high quality of the work submitted by him to the adjudicators.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Aitiology*, Westrand, London; telephone, 2630, Gerrard.

2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.

3. MEDICAL SECRETARY, *Mediscera*, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Jacillus, Dublin*); telephone, 4737, Dublin, and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

QUERIES AND ANSWERS.

"W. H. B." asks for advice in the treatment of an obstinate case of pityriasis rubra.

INCOME TAX.

"CUSTOMS" is in the service of a borough council. For 1919-20 he was first assessed on the salary payable for that year; later an additional assessment was made on a bonus which was in force for a portion of 1919-20, and now a further charge is raised to cancel certain allowances which ceased to apply at the higher amount of income.

Our correspondent not unnaturally resents such repeated applications, but unfortunately he has no remedy. The Revenue authorities are entitled to correct an assessment within three years, and if his total income for 1919-20 exceeded £800 the cancellation of the allowances is legally justified. If that total exceeded £800 but not £1,000 he is entitled to an allowance for each child—in excess of two—who is a proper subject of claim—for example, if the allowance for three children has been cancelled £40 for one child should be restored.

LETTERS, NOTES, ETC.

HERPES AND VARICELLA.

DR. H. B. WILLOUGHBY SMITH (Gainsborough) writes: I have recently had an interesting instance of the association or possible connexion between herpes zoster and varicella. Early in January this year I was called to see a boy, aged 7 years, who had a very well-marked eruption of herpes zoster, covering practically the whole of the area supplied by the third dorsal on the left side. Exactly twenty-one days later this boy's young sister developed a typical varicella eruption over the whole body. There are no cases of varicella in the vicinity, and neither child had been exposed to any possible outside infection. The connexion appears too close to be mere coincidence.

DR. ST. GEORGE B. DELISLE GRAY (Medical Officer, British Hospital, Oporto) writes: It may be of interest to add the following two cases to the many already published of the association of herpes with varicella. There was an epidemic of chicken-pox last year in Oporto. Towards the beginning of this epidemic I was called in to see a little girl who had typical varicella. On making enquiries as to contacts and other members of the

family the mother volunteered the statement that about a fortnight before she had had similar spots "on one side of the body which I thought was shingles." I have no doubt that she was right in her diagnosis. The other two child members of the family had chicken-pox in due course. About the same time I was consulted by the head of a school, who had a severe attack of herpes. A fortnight later there was an outbreak of chicken-pox at the school among the boarders at his house.

TUBERCULIN IN ASTHMA.

DR. F. E. GUNTER, D.S.O. (London, W.) writes: I was much interested in Dr. J. L. Rentoul's letter of February 4th, p. 212, on the use of tuberculin in asthma. He states that some cases do well but not all. The reason for this probably is that by no means all cases of asthma are of tuberculous origin. I test my cases with T.A.F. after the method advocated by Dr. Camac Wilkinson. If they react then I treat them either with P.T.O., which is excellent, or some other tuberculin preparation. If there is no reaction it is wiser to look for another cause of the asthma, such as some food idiosyncrasy.

DEPILATORIES.

A CORRESPONDENT, who has a lady patient with marked growth of hair on the chin, writes to inquire about an efficient depilatory. We published in 1920 (August 7th, August 21st, and September 11th) some notes upon this subject, which may be summarized as follows: The most satisfactory method of removal from the upper lip and chin is apparently by electrolysis; this, however, has the drawback that a slight degree of scarring is probable, while a certain percentage of hairs usually return at a later date. A depilatory powder which has been recommended consists of equal parts of barium sulphide and zinc oxide; this is made into a thick paste with water immediately before using. The directions are to rub the paste upon the lip or chin, and leave it on until it causes a slight smarting (one or two minutes); it is then washed off with water and some soothing ointment applied; the hair can be rubbed off in about ten minutes. A second, or even a third, application may be necessary, and it is better to go slowly than to risk wounding the skin by leaving the paste on too long the first time. Another correspondent wrote asking if there was any real objection to shaving with a safety razor. He had recommended this to two lady patients, with complete satisfaction to them as regards the result; of course it had to be done at fairly frequent intervals.

Our correspondent, therefore, can have his choice of treatments, but, as depilatory powders are really only a form of shaving, it is difficult to see any objection to the use of a safety razor, and even the best depilatories are apt to cause some irritation of the skin.

PELIOSIS RHEUMATICA.

A Correction.

DR. F. G. CLEMON, C.M.G. (Constantinople), writes: A small but unfortunate misprint occurs in my letter on this subject, which you were good enough to publish in your issue of January 28th (p. 168), and I shall be much obliged if you will allow me to make the following correction. The penultimate sentence should read: "Unfortunately, neither the patient nor his friends had realized the gravity of the condition and sent for me during the twenty-six or twenty-seven hours. . . ." My object was to state that patient and friends did not realize the gravity of the condition, and did not send for me, whereas the letter as printed exactly reverses the latter statement.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 32, 33, 36, 37, 38, and 39 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 34 and 35.

THE Home Secretary proposes to appoint a physician as medical referee under the Workmen's Compensation Act, 1906, for County Court Circuit No. 32 (Norfolk). Applications to the Private Secretary, Home Office, by February 21st.

THE following vacant appointments of certifying factory surgeons are announced: Cheltenham (Gloucester), Pollokshaws (Lanark), Topsham (Devon), Wool (Dorset).

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	0 9 0
Each additional line	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 15 0
Half page	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *poste restante* letters addressed either in initials or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

127. Hypertonus and Diabetes.

KYLIN (*Zentralbl. f. inn. Med.*, November 12th, 1921) examined the blood pressure of 58 cases of diabetes, 42 of whom were above and 16 below 40 years of age, and found that in the juvenile form of diabetes the blood pressure was usually within normal limits, whereas in the senile form a rise of blood pressure was the rule, almost 50 per cent. of all the cases in this group having a blood pressure of 180 mm. Hg or above. The readings, however, varied considerably in the same individual, as was shown by taking the readings both in the morning and the evening. The almost invariable existence of hypertension in senile diabetes suggested to Kylin that in cases of hypertension in which there was no glycosuria there might be nevertheless a diminished tolerance for carbohydrates, and that cases of hypertension without glycosuria might later be transformed into diabetes mellitus. He has, indeed, observed a woman aged 44 who was under treatment in 1919 for simple nephrosclerosis, and was admitted to hospital in 1920 for diabetes mellitus. He has recently begun to test the carbohydrate tolerance of cases of hypertension, and has occasionally found a diminished tolerance for carbohydrates, though not enough for glycosuria to appear when the patient was on ordinary diet. As the tendency to a rise of blood pressure and a diminished tolerance for carbohydrates often appears to occur in advanced life, Kylin suggests that the same morbid process—namely, an anomaly of the internal secretions—is the cause of both symptoms. It is well known that in certain endocrine disturbances, such as Graves's disease, myxoedema, acromegaly, and, according to some authorities, in diabetes also, there is an increase of lymphocytes in the blood. Kylin has therefore made an investigation to see if the same change occurred in hypertension also, and found that of 16 cases examined all but two showed a lymphocytosis of from 40 to 50 per cent. As the significance of lymphocytosis is not yet established, Kylin does not wish to draw any conclusions from this, but points out that the hypothesis of an endocrine anomaly being the cause of simple arterial hypertension is supported by the blood picture.

129. Syphilis without a Chancre.

GONGEROT (Bull., et Mém. Soc. Méd. des Hôp. de Paris, November 24th, 1921) remarks that the question of syphilis without a chancre in the adult is still unsettled, some authorities, such as Fournier, denying the existence of such cases, and maintaining that the chancre is always present though it may be deeply situated, of transient duration, of minute and even microscopical size, or be mistaken for a scratch, gonorrhoea, tonsillitis, etc. Others believe in infection by a visceral route, such as contamination of the uterine mœosa, infection of the peritoneum by the surgeon's hand during an operation, or ingestion of infected food. There are, however, undoubted cases of cutaneous inoculation of syphilis without a visible chancre, as in infection following therapeutical injections without antiseptic precautions, and infection in the laboratory or of the surgeon's hands during an operation. Gougerot reports two cases of acquired syphilis without a chancre, in one of which there was a suppurating bubo and in the other an induration of the inguinal glands, bacteriological examination of the adenitis showing the *Spirochaeta pallida* in each case. In both, the lesions subsided rapidly under specific treatment. In a subsequent paper Gougerot (Ibid.) records four examples of mixed infection—that is, syphilis associated with chancreoid. In each case the patient presented a suppurating bubo without any trace of a chancre, and well-marked symptoms of secondary syphilis developed later.

129. Late Recovery from Katatonia.

129. Late Recovery from Katatonia.
HAVERKATE (Nederl. Tijdschr. v. Geneesk., October 15th, 1921) states that very little is to be found in textbooks of psychiatry about late recovery from katatonia. Kraepelin states that in 13 per cent. of the cases recovery takes place, or at least improvement bordering on recovery, but that a relapse is very likely to occur, even after an interval of ten to twenty years. The duration of improvement is usually two to three years, but it may be nine to sixteen years, and Kraepelin has seen a case of recurrence after twenty-nine years. In Racok's series of 200 cases of katatonia the duration of cases ending in recovery was rarely more than two years; 46 of the 200 recovered, but in only 3 of these had the disease lasted three

to four years, and cases of recovery with a duration of illness of more than four years were not observed. Kreuser in 1930 reported 12 cases of recovery from katatonia in which the disease had lasted more than seven years, and 21 recoveries in which it had lasted from four to seven years. The case of longest duration in which Kreuser had seen recovery take place was twenty-one years. The longest duration of a case on record of katatonia which finally recovered is that reported by Fromme in which the disease had lasted thirty years. As a rule, however, katatonia seldom ends in recovery after it has lasted two years. Haverkate reports the case of a man, aged 34, who made a good recovery from katatonia after eight years' illness, and was able to obtain work as clerk in an insurance office and obtain promotion, his mental condition being good at the time of publication, two years after his recovery.

130. Bird-Mite Dermatitis.

Grön (Tidsskrift for Den Norske Lægeforening, December 1st, 1921) describes a small epidemic of scabies-like itching, due to the bird mite (*Dermanyssus gallinac*), which is popularly known as the dove louse. It is a little over 1.2 mm. long—that is, it is hardly as large as a pin's head. It hides by day in dovecots and hen-houses, coming out at night to suck blood. Its range of movement is considerable, but it does not, like the scabies mite, dig itself into the skin. The first case seen by the author was a man, aged 48, with an extensive eruption over the body and arms. It resembled in every respect the eruption of scabies, with this one exception, that there were no burrows. He stated that he, his wife, his son, and a niece lived under a loft to which numerous doves had access. There were cracks in the floor of this loft, and examination of a specimen of the numerous small, grey, movable, dust-like granules found on the bedding showed it to be the parasite under discussion. All four persons concerned suffered from itching and an eruption. Under treatment with a scabies ointment the itching rapidly diminished, but even ten days later the eruption had not disappeared. The author cites various Norwegian authorities to show that this form of dermatitis is comparatively common in several parts of Norway. In the treatment of such cases it is not necessary to be so thorough in the use of ointments as in the case of scabies, and the mite can be successfully disposed of by sulphur fumigation, closing cracks in floors and walls, and by applying lime to the wood-work of infected buildings.

131. Silver Arsphenamine.

131. *Silver Arspheaminæ.*
BERGHAUSEN (*Med. Record*, November 28th, 1921) calls attention to the therapeutic value of silver salvarsan (the sodium salt of silver-diaminodihydroxyarseno-benzene, in which the silver is in non-ionizable form) in the treatment of syphilis, from an experience of 133 injections. Severe reactions should be avoided by the repetition of small doses, unless the tolerance of the individual has been previously determined. The initial dose was usually 0.1 gram, followed in four or five days by 0.2 gram, and then by 0.3 gram if no reactions occurred, and in the whole series only three reactions were obtained, two of which were slight, the third being accompanied by diarrhoea in a paretic who had been unable to tolerate arsenic preparations and mercury. Improvement followed in the primary, congenital, and cerebro-spinal cases, and some improvement was noted in 50 per cent. of the tabetics. In two cases the intravenous injections were followed by intraspinal ones without reaction. The absence of headaches and gastro-intestinal disturbances made patients more readily undergo further treatment, especially those who had been unable to take arsenamine or neo-arsphenamine without the occurrence of such symptoms, and the improvement noted was as marked as that following the use of the older preparations.

132. A Mental Form of Epidemic Encephalitis.

132. **A Mental Form of Epidemic Encephalitis.**
 DELATER and ROTQUIER (*Bull. et Mém. Soc. Méd. et N. p. de Paris*, November 17th, 1921) state that a form of epidemic encephalitis characterized by exclusively psychical symptoms had been described by one of them in 1920, and since by numerous writers, including (Lande, Froment and Comte, Abadie and Hespard, and Guy Larode and Médail. Localizing signs in the central grey nuclei, pons, and medulla are either absent or take a very secondary place. Delirium, hallucinations, confusion, and mental disturbances of all kinds dominate the scene, and the diagnosis can only be established by the subsequent appearance of transient and

dissociated paralyses, myoclonus, and sometimes neuralgic symptoms. The writers report the first case on record in which the post-mortem examination of such a case confirmed the diagnosis made during life of epidemic encephalitis. No neurological symptoms were detected during life, and at the autopsy the lesions were confined to the cortex and meninges.

133. The Treatment of Post-Encephalitic Insomnia.

LUST (*Deut. med. Woch.*, December 22nd, 1921) confirms the observation, made by Adam at Heidelberg, that intramuscular injections of milk promptly induce sleep in children whose post-encephalitic insomnia has proved refractory to the usual remedies. In one of the author's cases typical epidemic encephalitis had left the child with severe restlessness and insomnia at night. This condition had lasted for more than a year, but as soon as an intramuscular injection of 2 c.cm. of boiled milk gave rise to a febrile reaction the child fell asleep and did not wake till twelve hours later. Numerous observations with a rectal thermometer showed that sleep began only when the temperature rose above the normal, and lasted only as long as it was raised; as soon as it reached normal the child awoke. He also proved that there was nothing specific in the soporific action of these injections, for when they failed to provoke fever, or when a febrile reaction was aborted by antipyrin, no sleep was induced. Other artificial means for raising the temperature, such as hot baths, also secured sound sleep. When injections of distilled water were substituted for the injections of milk sleep did not follow; this indicated that there was no element of suggestion in the success achieved. The author concludes that the hypothetical sleep centre must be situated close to the heat regulation centre.

134. Serum Treatment of Diphtheria.

ACCORDING TO LEREBOLLETT (*Paris méd.*, November 5th, 1921), every case of diphtheria should be treated at once by an intramuscular injection of 20 to 60 c.cm. of autitoxin according to the age of the patient and severity and duration of the disease. The intramuscular injection should be accompanied by a simultaneous subcutaneous injection, and the latter should be repeated during the following days with or without further intramuscular injections. In severe cases the injections should be continued for several days, even after disappearance of the membrane, so as to prolong the duration of immunity. The doses should be regulated by the severity of the disease and the date at which treatment began, without fear of giving large doses, even as much as 100 c.cm., repeated two or three times in severe and late cases. In mild and early cases the doses may be considerably less.

SURGERY.

135. Plastic Operations on the Lip.

MOOREHEAD, BROWN, and KAZANJIAN (*Journ. Amer. Med. Assoc.*, December 17th, 1921), in different articles, discuss plastic operations on the lip for the treatment of hare-lip and reconstruction after war injuries. The treatment of congenital cleft of the hard palate, when associated with hare-lip, should be undertaken at the earliest possible age—that is, from six to ten weeks after birth. One of the major problems is that of feeding, and the nipple should never be used, as sucking causes a certain amount of bone separation which is reflected in the nostril. During the operation an aspirator is used to keep blood out of the throat. The first step in the operation is to complete the anatomic restoration of the arch by moulding, and the bones are transfixed by a wire suture. By dissecting the lips and cheeks freely from the bone a well-shaped nostril is secured. This aids the shaping of the lip, which is done at a later date. The cosmetic results of the hare-lip operation depend on the degree in which the associated nasal defects have been overcome. In surgical correction there are two elements to be considered: Arrest of development, which created the deformity, and perverted growth due to malposition. Successful treatment depends on the accuracy with which normal anatomic conditions may be restored. Normal relations should not be disturbed or underlying bone destroyed in efforts to close the fissure. In the treatment of reconstruction of the lip following loss of tissue as the result of injury, the earlier the wound can be sutured the better would seem to be the result. These wounds are usually septic, and sepsis must be controlled before undertaking a serious plastic operation. Where there is loss of bony substance, the lost bony tissue must be restored or replaced by some mechanical appliance before successful cosmetic results can be obtained. Loss of tissue may be replaced from the immediate vicinity or from more

distant parts, such as the neck. The inner lining of the lip, as well as the red border, must be restored, otherwise distortion will result. Every case of plastic reconstruction must be executed on its own merits and different procedures attempted in extreme cases. One must have in mind from the first the desired results, and all preliminary operations should lead up to the main procedure.

136. "Spontaneous" Rupture of the Extensor Longus Pollicis Tendon after Colles's Fracture.

STAPELMOHR (*Acta Scandinavica*, November 16th, 1921) has reported three weeks of each other, two cases in which, some time after a typical Colles's fracture, the tendon of the long extensor of the thumb suddenly gave way on very slight provocation. Being unfamiliar with this complication of a Colles's fracture he feared that in his first case he might have injured this tendon while he was setting the fracture. He realized this fear was ungrounded when, in his second case, this rupture occurred in spite of the fact that, no displacement of the bone having been caused by the fracture, he had not manipulated it. A study of the literature showed him that eight similar cases have been recorded. Though rare, this complication presents a well-defined clinical picture. After an interval of a few weeks, during which the Colles's fracture seems to have left the movements of the thumb unimpaired, the tendon of the long extensor suddenly gives way in response to quite a slight effort, such as jabbing a hatpin into a hat. The author suggests that, when the fracture occurs, the hand is extended and the thumb sharply abducted in the patient's effort to save himself as he falls. This more or less automatic effort brings the tendon of the long extensor suddenly and forcibly against the distal end of its sheath, on which it is more or less kinked. The involuntary contraction of its muscle adds further to the pressure suddenly put upon it at this point. The result is slow necrosis of the tendon with little or no inflammatory reaction. The ages of the ten patients who developed this complication ranged from 26 to 60 years, and the author points out that the blood supply of the tendon is comparatively poor after the twenty-fifth year, and thus facilities for regeneration are less adequate than in childhood and adolescence.

137. Intracardiac Injections of Adrenaline in Acute Heart Failure.

KNEIER (*Deut. med. Woch.*, December 8th, 1921) considers that the outfit of a general anaesthetist is incomplete without adrenaline ready for injection into the cavity of the heart. He notes that about eighteen cases have already been recorded in which permanent effects were achieved by adrenaline given in this manner, and he records two cases, in the first of which the intracardiac injection failed of its object. In the second case it was dramatically successful. The patient was undergoing an operation for cancer of the larynx under local anaesthesia, supplemented by morphine and atropine, when respiration suddenly ceased. The colour of the face was at first cyanosed, then pale. The pupils were dilated and incapable of reaction, the pulse was not palpable. Artificial respiration, oxygen inhalation, cardiac massage, and the subcutaneous injection of stimulants proved futile. About four minutes after respiration had ceased, 1 c.cm. of suprarenin was injected into the cavity of the heart. Half a minute later pallor gave way to a flush, the pupils slowly contracted, and the pulse could again be felt. The first active respiratory movement occurred about a minute and a half after the injection. The operation was resumed, but eighteen days later the patient died suddenly from pulmonary embolism due to thrombosis in the right leg. The heart and pericardium showed, at the necropsy, no evidence of injury from the injection. The author concludes from his and other published cases that serious injury to the heart need not be anticipated, and that, provided respiration has not stopped for more than five minutes, the injection may save the patient's life. The technique is simple, a needle being thrust into the fourth intercostal space close to the left border of the sternum. If the operator aspirates as he thrusts the needle into the heart, the free flow of blood into the syringe will tell him when he has reached the cavity of the heart.

138. Treatment of Acute and Chronic Pancreatitis.

LUND (*Boston Med. and Surg. Journ.*, December 29th, 1921) reminds us that it was Opie who, in 1901, after an autopsy on a case of acute pancreatitis, first showed that blocking of the ampulla of Vater with a small gall stone might cause infected bile to ascend into the pancreas and set up an acute inflammation. As a result of this it was suggested that drainage of the bile might be the best treatment for acute pancreatitis. Later it was found that only in a few cases was it possible for a stone, though not seen at the autopsy, to

have blocked the duct long enough to cause acute pancreatitis and then be passed. So it becomes evident that in certain cases the presence of blocking stones in the papilla could not have caused the disease, nor could drainage of the bile system effect a cure. Subsequently surgeons, when operating upon the abdomen, began to observe variations in the size and consistency of the pancreas, which were believed to be inflammatory from infected bile, and they treated these conditions by drainage through a cholecystostomy. Now the present-day view of gall-bladder disease is that the primary infection reaches the gall bladder through the lymphatics or vessels from the liver. In cholecystitis we invariably find the gland at the neck of the gall bladder swollen. The lymphatics from here anastomose freely with those of the head of the pancreas. An invasion of the pancreatic lymphatics from the inflamed gall bladder or stomach would explain cases of acute and chronic pancreatitis not explained by invasion from the ducts. Such a theory suggests for the treatment of chronic pancreatitis not a drainage of the infected bile, but a removal of the source of infection by a cholecystectomy. In cases where jaundice is present and there is doubt as to the presence of a stone in the common duct, it is wiser to drain the gall bladder. In patients thoroughly toxic at the beginning of an attack it has been advised to leave them, so that the process may become walled off, and then drain. But it is often wiser to operate in the acute stage, and drainage of the infected secretion may save the patient. Carcinoma of the pancreas is frequently hard to differentiate from chronic pancreatitis. In both cases, where jaundice is present, a cholecystenterostomy often gives great relief.

139 Division of the Spermatie Vessels for Undescended Testicle.

KUTTNER (*Zentralbl. f. Chir.*, October 29th, 1921) partially repeats his earlier recommendation of an operation for undescended testicle, the chief feature of which is division of the vessels of the spermatic cord. As a rule he has found the atrophic undescended testicle develop satisfactorily when secured in its normal position after division of the vessels of the cord, and in some cases patients have told him that the operation was followed by increased potentia coeundi. His enthusiasm for this treatment was, however, damped by two cases. In the first, a young man, aged 18, was operated on for bilateral retention of the testicles. A year later the right testicle had grown to normal size and was in its normal position, but the left testicle had dwindled to a small band, palpation of which provoked the characteristic sensation associated with the testicle. The second patient, a man of 20, was found to have a much atrophied testicle, of the size of a hazel nut, at the level of the internal inguinal ring. After division of the vessels of the cord, the testicle was secured in the scrotum. Eighteen months later this testicle could not be found in the scrotum, although it was impossible for the testicle to have slipped back into the abdomen. The author points out that the atrophic testicle in this case might just as well have been removed at once instead of being left to atrophy in the scrotum. He notes that, besides these two failures, he has had numerous successes, and he considers that the operation is indicated when the testicle is far from the scrotum and other less radical methods have failed. When the condition is bilateral, as in his first case, he advises against the simultaneous performance of this operation.

140. Typhoid Spondylitis.

ACCORDING TO BOOT (*Nederl. Tijdschr. v. Geneesk.*, October 22nd, 1921) of Amsterdam, who records an illustrative case in a girl aged 16, which developed about six weeks after an attack of typhoid fever, this is the first Dutch case which has been published in the *Tijdschrift*, although at least 20 cases have been recorded in German literature and about 70 in English. Quinke, who first described the condition in 1899, regarded the following symptoms as typical: (1) Extremes severity and extent of the spontaneous local pain; (2) extensive swelling of the soft parts; (3) acute febrile course. In Boot's case, in which the body of the third lumbar vertebra was involved, swelling of the soft parts was the only symptom absent. Cases of typhoid spino may be classified in four groups. The first consists of the mildest cases, in which X-ray examination is negative. Boot's case is an example of the second group. The third group consists of severe cases, in which kyphosis and paralysis may occur. To the fourth group belong the cases of spondylitis of which Wilson's case, reported in 1909, is an example. In such cases the swelling of the soft parts predominates, so that the condition may be mistaken for one of renal abscess. Usually the lumbar vertebrae are affected, but the thoracic vertebrae may also be involved, as in Lyon's case, in which the ninth to twelfth thoracic vertebrae and the first to fifth lumbar vertebrae were affected. Spondylitis may occur as late as six months after an attack of typhoid fever. Sometimes it develops after a trauma, but it may appear, as in Boot's

case, without any such history. The prognosis is favourable, with the exception of those cases in which kyphosis or paralysis occur. Treatment consists in keeping the patient supine for about two months, and then making him wear a plaster jacket for another three months.

141.

Fractures of the Ulnar Styloid.

WAKELEY (*Arch. Radiol. and Electrotherapy*, October, 1921) describes fracture of the styloid process of the ulna, occurring somewhat rarely as a single lesion caused by direct violence, with occasionally a history of a twist. Since these fractures, and those of the carpal scaphoid, can generally only be diagnosed with certainty from sprains of the wrist by means of X-rays, a plate should be taken as a routine in all cases of wrist injury. If seen soon after injury there is some oedema, swelling, and tenderness of the part, with limitation of dorsiflexion of the wrist and absence of crepitus, the radial styloid process being generally at a lower level when compared with the other hand. Three weeks in dorsiflexion with slight ulnar deviation on a "cock-up" splint is necessary, after which massage with the splint *in situ* should be given for another week, when the splint may be discarded.

OBSTETRICS AND GYNAECOLOGY.

142. Pathology of Haemorrhage from the Non-Pregnant Uterus.

SCOTT (*Amer. Journ. of Obstet. and Gynec.*, November, 1921) has examined histologically the myometrium and endometrium in 92 cases characterized clinically by haemorrhage from the non-pregnant uterus in the absence of neoplasm; the macroscopic as well as the microscopic findings were inconstant. In sixty-two instances the uterus had the gross characteristics of the so-called fibros uteri; the walls were much thicker than normal, and the blood vessels projected from the cut surface. In 16 cases the uteri, although firm in consistency, was smaller than normal, and in 14 cases it was the ordinary size. Microscopically the proportion of fibrous tissue in the uterine wall appeared to be increased in 34 cases, diminished in 2, and normal in the remaining 56. Thickening of the blood vessels was equally inconstant. In 34 control cases not characterized clinically by excessive bleeding the gross and minute characters varied in approximately similar proportions. It is concluded that the bleeding is not actually caused by any one of the changes described either in the myometrium or the blood vessels; the one finding, however, that was more constantly present in the bleeding cases than the others was that of glandular hyperplasia of the endometrium, which in the great majority of cases was much thicker than normal. On the following grounds it is regarded as probable that the cases of bleeding under consideration are due to some aberration of the endocrine glands. Idiopathic haemorrhage occurs only during menstrual life, and nearly always begins as a menorrhagia; it occurs most frequently near the time of puberty or the menopause at a time when the action of the endocrine glands is most frequently abnormal; it sometimes disappears without apparent cause; certain ovarian conditions, such as lutein cysts, are commonly associated with both bleeding and glandular hyperplasia of the endometrium; finally, the condition can be cured by X-ray or radium therapy, the action of which is primarily on the ovaries.

143. A Method of Intrapelvic Radium Therapy.

DAELS (*Gynec. et Obstet.*, 1921, iv, 5) describes a method of applying radium within the true pelvis by passing a drainage tube containing tubes of radium along a curved course beginning at the side of the anus and ending near the crest of the ilium. Appropriate courses have been devised for similar treatment of rectal and vesical cancer and for cancer of the prostate in the male; the object of the procedure is to destroy neoplastic tissue in the lymphatic glands and channels which are affected by the extension of the growth. The technique of the course of "radium-therapeutic drainage of the small pelvis" for cancer of the cervix uteri—a course which has the terminations already mentioned—is as follows: Under spinal anaesthesia the patient is placed in the gynaecological position and an incision is made a little behind the tuber ischii between that prominence and the anus. By blunt dissection the finger is made to penetrate the ischio-rectal fossa and is directed towards the lower border of the great sacro-sciatic ligament, covered by the coccygeal portion of the levator ani; it then passes in front of and internal to the spine of the ischium between the iliac and coccygeal parts of the levator towards the sacro-iliac joint. A graduated semicircular sound is passed along the track thus made. From an incision internal to the anterior part of the iliac crest a finger is now passed extraperitoneally in the false

pelvis in front of the iliacus and psoas muscles, behind the iliac vessels, towards the sacro-iliac joint. The end of the sound is then passed in the direction of this joint and the sound is drawn forwards and outwards so as to emerge at the second incision. Within an indiarubber tube of length a little more than that of the true pelvis from the innominate line to the spine of the ischium (as calculated by measurements along the graduated sound) are placed one or more tubes containing radium, and a chain is attached to each end of the tube. One end of the chain is fixed to the sound, and the chain and indiarubber tube are made to replace the sound, and are left in the track through the pelvis. A similar procedure is carried out on the other side. The precise dosage is not stated, and Dael's is not yet prepared to formulate the exact indications for this treatment. His present treatment is, for inoperable cases, ennetting and bilateral "radium therapeutic drainage" at one sitting; and for operable cases, vaginal hysterectomy and bilateral drainage at one sitting, followed a few days later by vaginal irradiation. Three cases of recurrence after hysterectomy, eleven inoperable cases, and two operable cases in obese subjects have been treated by Dael's method during the last twelve months, without operative complications, and with a post-operative mortality of two, due respectively to intestinal obstruction caused by adhesions to the scar of vaginal hysterectomy and to secondary haemorrhage. Other post-operative complications were suppuration (occurring in some instances in the drainage track as late as the fourth week), transitory neuritis, fistula (attributable to the operation rather than the irradiation, in one instance only), and rectal ulceration. In general, pronounced improvement of local and general symptoms and signs has followed.

144. Morphine, Strychnine, and Caffeine in Labour.

CHIMICHIAMO (*Revista d'Obstet. e Ginec. Practica*, April, 1921) in four cases has had satisfactory results from intramuscular injection, repeated once if necessary, of 1 c.cm. of a solution containing 0.03 cg. morphine hydrochloride, 0.003 mg. strychnine sulphate, and 0.05 cg. caffeine. In one patient, a hysterical subject who was convulsed, labour terminated spontaneously twenty-five minutes after the injection: in the others it became possible, quietly and without giving pain, to perform version or forceps extraction. The injections must not be given before the cervix has become thinned and a dilatation of at least 3 cm. has occurred. The author concludes that, carefully given, the treatment has a limited but useful application, rendering the uterine contractions stronger, but less frequent, and diminishing the consciousness and sensibility of the patient. In the doses named, the drugs are considered to be without toxic effect on the mother and child; the action became manifest in from eleven to twenty-eight minutes.

PATHOLOGY.

145. Lymphatic Diseases.

THE neglect of the study of disease of the lymphatics shown by both physiologists and pathologists is emphasized by JACOBSON (*Albany Medical Annals*, December, 1921). The author, in discussing Hodgkin's disease and lymphocytic leukaemia, suggests that chronic irritation may operate in the same way in causing these diseases as it does in the production of many epithelial and connective tissue tumours. In Hodgkin's disease the pleomorphic diphtheroid bacillus described by Bunting may be the irritating cause. But whatever be the source of the chronic irritation, bacterial or toxic, the effect on so capricious a tissue as that of the lymph nodes may be expected to show itself in various ways at different ages of the individual. In youth lymph nodes become enlarged under the influence of various irritants. During the first two decades of life a leukaemic blood picture is rarely met with, the obvious effect of the toxic agent being confined to the lymph nodes. Hodgkin's disease being a disease of youth, and leukaemia being more frequent after the thirtieth year, the author suggests that in youth the lymphocytes are more susceptible to destruction than in adult life, when, as they are not so easily destroyed, they are poured forth into the blood stream.

146. The Antiphlogistic Action of Calcium Salts.

IN 1896 Wright pointed out the effect produced by the administration of calcium chloride in preventing certain cutaneous inflammations, such as the urticaria following on the injection of serum and the localized oedemas provoked by the inoculation of bacterial vaccines, and ascribed this effect to the action of this salt on the coagulation of the blood. At a later date Chiari and Jantschke, while showing the

fallacy of this hypothesis, suggested that the calcium acted by decreasing the permeability of the capillary walls and thus preventing the egress of plasma and cells. The subject has now been taken up by BLUM (*C. R. Soc. Biologie*, December 17th, 1921), who, though confirming the results of previous workers, is led to draw a different conclusion from the experiments on which they were based. If a drop of mustard oil be placed in the conjunctival sac of a rabbit an intense inflammation is produced. If now an intravenous injection of calcium chloride be given, the inflammation rapidly subsides and the eye returns to normal. If, however, a simultaneous dose of sodium chloride be administered no effect is produced. The sodium and the calcium exert antagonistic effects. While the rabbit is in a state refractory to inflammation, consequent on the exhibition of calcium chloride, it is found that the titre of sodium in the blood is diminished. Now, as water and sodium chloride are both necessary to the formation of an exudate, it is clear that if their availability for reaction processes can be interfered with, no exudate will be formed. It is an action of this kind that Blum attributes to calcium salts.

147. The Serological Differentiation of some Strains of *B. diphtheriae*.

BELL (*Journ. R.A.M.C.*, January, 1922) has tested the agglutination reactions of 130 strains of *B. diphtheriae*, the majority of which had been isolated from patients and carriers during the recent outbreak in the London district. Altogether thirteen serums were prepared, and by their use it was found possible to classify 80 per cent. of the strains into three groups. Of these, Type I contained 13 per cent.; Type II, 6 per cent.; and Type III, 61 per cent. The results in some cases were confirmed by the absorption reaction. No correlation could be determined between the serological type and the virulence of the organisms. Moreover, so far as could be judged from protection experiments, the toxin secreted by organisms belonging to different types was the same. That is to say, that whereas the bacterial antigen is specific, the toxin antigen is non-specific. It is of interest to recall in this connexion that Tulloch reported similar findings in his work on tetanus bacilli, the organisms being classifiable into four types, yet the toxin formed by them being common to all.

148. Melioidosis, a New Disease of the Tropics.

IN a short paper (read before the Far Eastern Association of Tropical Medicine, Batavia, 1921) STANTON and FLETCHER distinguish a new disease resembling glanders, for which they propose the name "melioidosis," because the Greek physicians described under the name "melis" a number of conditions resembling glanders. The causative organism, a bacillus, was first described by Whitmore in 1912, who isolated it *post mortem* from a number of cases in which the lesions resembled those met with in glanders in the human subject. Stanton recovered the same organism from patients dying of septicaemia after Asiatic cholera. The organism was excreted in the faeces and urine, and the disease could be conveyed to laboratory animals, reproducing in them typical lesions. Recently the organism was isolated from cases of chronic inflammation and abscess formation, and the blood serum of such patients has been found to agglutinate *Bacillus whitmori* to a titre of 1 in 2,000. Further particulars with regard to the bacillus and the clinical lesions are promised in the *Transactions* of the Congress.

149. Surface Tension and the Action of Antiseptics.

HANSEN (*Hospitalstidende*, October 19th and 26th, 1921) has carried out a long series of investigations at the Pathological Institute of the University of Copenhagen into the relation of surface tension of disinfectants to their antiseptic action. He found that the great addition to the effectiveness of such antiseptics as carbolic acid made by combining them with weak solutions of alcohol was proportional to the diminution of the surface tension. It is difficult to account for this increase in the antiseptic action of disinfectants; it cannot be due simply to the sum of the disinfectant action of alcohol and carbolic acid, for 5 per cent. alcohol has no disinfectant action whatever. Yet its addition to an ordinary antiseptic greatly enhances the latter's action. By the addition of 10 to 20 per cent. of ethyl alcohol or of 5 to 10 per cent. of propyl alcohol to HCl, carbolic acid, mercury perchloride, or chromic acid, the author found that their disinfectant action was enormously increased, and in the case of a solution of HCl he found that it took twenty-nine and three-quarters hours to kill anthrax spores, but less than half an hour was required when, to the same strength of HCl, 70 per cent. of ethyl alcohol was added. By itself 70 per cent. ethyl alcohol took more than thirty-one hours to kill these spores.

Remarks

ON

OBSCURE INTESTINAL COLIC.*

BY

H. TYRRELL GRAY, M.A., M.Ch. Cantab.,
F.R.C.S. Eng.SURGEON TO THE WEST LONDON HOSPITAL, TO THE HOSPITAL FOR SICK
CHILDREN, GREAT ORMOND STREET, AND TO THE
ITALIAN HOSPITAL.

"INTESTINAL COLIC" may be defined as pain which occurs only during peristaltic contractions, and is absent during the quieter continuous rhythmic movements.

The gastro-intestinal tract is a series of organs whose secretory and motor properties are controlled by a complex system of mutually antagonistic nerve impulses; which are influenced simultaneously by mutually antagonistic hormones; and which nevertheless possess inherent automatic rhythmic properties independent of such influences. Such a complex system of control of an automatic propelling, secretory and digestive apparatus is clearly designed to maintain a normal equilibrium in the presence of variable mechanical vascular or chemical conditions; and evidence is abundant that the normal gastro-intestinal tract adequately performs its allotted functions, not in obedience to, but independent (and often in defiance) of, mechanical laws.

Of the truth of this I need only give one illustration—namely, the well known law that any increase of mechanical opposition to the passage of contents (that is, any degree of obstruction) is invariably followed by overaction and hypertrophy on the proximal side; while, conversely, it is a sound deduction that the final test of any mechanical obstruction is the presence of proximal hypertrophy. The clinical value of this law is that abnormal delay in the passage of contents through the intestinal tract must never be attributed primarily to mechanical opposition unless evidence of such overaction or hypertrophy is present.

The complexity of the subject is enhanced by the fact that, as in the species the alimentary tract is modified to suit the character of the food, so in the individual are the different regions modified to meet the varying digestive requirements of the food in the successive stages of its transit.

Thus we should not expect identical or analogous mechanisms to prevail in different regions; and, indeed, we find a constant gradual alteration of every mechanism as we pass almost insensibly from the voluntary or controlled act (mastication and swallowing) to the involuntary (digestion and absorption) and return again to the voluntary (defaecation). It is interesting that in these transitions the changes of mechanism are always gradual and ill defined.

Thus, for example, it is significant that glandular secretion originally controlled by nervous mechanism, subsequently comes (in the stomach, pancreas, etc.) under the final influence of nerve both of which seem capable of exerting a later still—for example, the small intestine is at a minimum, and secretions are mainly excited by chemical and mechanical agencies (Langdon Brown).¹

As a parallel it is noteworthy that similar changes are observed in the motor mechanism. For the voluntary control of the passage of food is effected through the medium of a single nerve supply to the muscles concerned, while those of the gastro-intestinal tract are controlled by a dual antagonistic innervation and by hormones also. Finally, as the voluntary control of the motor functions is again gradually resumed (defaecation) a return to the single nerve supply of at least the chief muscles is to be noted.

When we come to consider the sensibility of the alimentary tract we should expect to find an analogous reversal of mechanism, and this expectation is again justified. Thus the highly developed special senses rapidly give way to a mere sensibility which, though present at the lower end of the oesophagus as shown by Hurst,² nevertheless progressively diminishes up to this point. Beyond this point (that is, in the stomach and intestines) sensibility is completely absent under normal conditions, as indeed is only to be expected of organs clearly designed for a vegetative function alone. I am well

aware of the contentious character of the ground I am treading on; but this statement is made deliberately. For, so far as I am aware, no conclusive evidence, whether clinical or experimental, has hitherto been brought forward to prove the sensibility of the gastro-intestinal tract until we approach once more the area of voluntary control—the desire for defaecation. The complete insensibility of the gastro-intestinal tract is further supported by the reflection that if the contrary were true, since normally sensation is (or should be) absent, under pathological conditions the sensation of pain would assume the existence of a mechanism designed for abnormal conditions only.

We all know how exceedingly difficult it may be—particularly in the child, but also in the adult—to appreciate the gravity or otherwise of obscure recurring colic; while, on the other hand, the catastrophe following on repeated warnings is painfully familiar. Is not much of this general uncertainty due to the fact that the structures concerned are themselves insensitive, and that consequently clinical examination is less instructive than in the case of structures whose sensibility is acute?

But if the intestine is insensitive, its blood supply and nerve supply are conveyed by a structure which is exceedingly sensitive to every kind of stimulus, mechanical, chemical, thermal, etc.—namely, the mesentery. Not only does clinical and experimental experience afford ample evidence of this, but histological evidence is to be found also in the presence of Pacinian corpuscles in this structure. Indeed, it is clear that this highly important structure is thus protected by adequate reflexes from any variations from the normal, particularly as regards pressure, tension, etc.

For many years I have believed and taught that all true visceral pain and discomfort arise from, and are primarily referred to, the mesentery, and that from this source it may or may not also be referred to the associated somatic nerves.

Thus, in the Arris and Gale Lectures, 1912, Dr. Parsons and I showed that mechanical stretching of the mesentery, the inevitable result of intestinal distension, was responsible for the afferent impulses causing typical blood pressure changes; while in other studies³ I have often adduced evidence that the mesentery is the sensitive structure.

In February, 1920, my Hunterian Lecture was devoted to showing that chemical and mechanical stimulation of the mesentery inhibits the normal motor functions of the gastro-intestinal tract, and is responsible for many of the disorders met with in clinical practice. In that lecture I attempted to show that surgery directed to the mesentery was every bit as important as that directed to the intestine itself, and that operations designed for the relief of abnormal mesenteric tension (that is, caecopexy, colopexy both "partial" and "complete," plastic lengthening of the mesentery, etc.) could so far abolish these pathological direct and reflex nerve impulses as to check or cure permanently the resulting intestinal disability, even after a considerable number of years. The contrast in severity between acute obstruction of the bowel itself and strangulation of the intestine and its mesentery, as well as the striking collapse attending the sudden escape of distended intestine during operations for acute obstruction, were emphasized as evidence that the mesentery (and not the intestine) is the sensitive structure.

Incidentally such observations hold good also in the case of the stomach, insensitive itself, but acutely sensitive in its mesentery (the gastro-hepatic omentum); and I hope shortly to produce evidence to show that not only is the pain or discomfort arising from gastric distension due to the stretching of this mesentery, but that such tension, by interfering with the venous return from the lesser curvature, is a most important factor in the etiology of gastric ulcer (for venous stasis is a common feature of chronic ulceration in any situation). But so wide is the application of this principle to the study of abdominal disease that we must this evening restrict our study to the mesenteric stimulation initiated by the peristaltic wave, which constitutes intestinal colic.

As a preliminary example, let us consider the pain caused by a simple stricture of the small intestine.

The characteristic feature in such cases is that the pain at first occurs at intervals, interrupted by periods of complete comfort. The normal intestinal lumen is so far as can be ascertained clinically, is negative; the pain is accentuated by and is due to the exaggeration of the rhythmic waves (as reflex) and these are responsible for exciting the vagus and continuous pain are absent, peristalsis and such a stricture, involving the circumference of the bowel, renders inactive a small segment of intestine which cannot take part in the co-ordinated sequence of contraction and inhibition, a sequence which constitutes the

* A paper read before the Hunterian Society.

essential feature of the peristaltic wave. Therefore, the contracting segment of the peristaltic wave immediately proximal to the stricture is not associated with the normal inhibition of the segment immediately below; so that the inert segment is forced into the lumen of the inhibited area below it. (Figs. 1 and 2.)

Such a tendency of the peristaltic wave to produce inversion or intussusception is prevented by the anchorage of the bowel to its mesentery; but the resulting tension on the sensitive mesentery induces pain by mechanical stimulation during the passage of the peristaltic wave.

This is the mechanism of intestinal colic, a pain associated with peristalsis; and it is not difficult to realize the potential gravity of such lesions, undetected by physical examination, not demonstrated by *x* rays, unassociated by gross disturbance of function, yet often steadily progressive, and culminating in an acute crisis due to the neglect of repeated warnings.

When is intestinal colic to be regarded as a grave warning, and when is it attributable to transitory causes? This decision must rest on our ability (as yet very imperfect) to appreciate the various factors responsible for disorganizing the co-ordinated sequence of contraction and inhibition in intestinal peristalsis, and to identify the primary causes of such disorganization.

These may be classified under four headings:

- (a) Abnormal contents within the lumen of the bowel.
- (b) Intramural lesions, or lesions of the wall of the bowel.
- (c) Lesions of the mesentery and peritoneum.
- (d) Alteration in the relative excitability of the sympathetic and parasympathetic nerve supply and the equilibrium normally influenced by their corresponding hormones.

The difference in mechanism between the small and large intestine makes it advisable to consider these separately.

SMALL INTESTINE.

(a) Abnormal Contents in the Lumen.

Normally the contents are fluid, and at intervals these attain sufficient bulk to excite by local pressure a peristaltic wave. When, however, any mass is present within the intestines of sufficient bulk to render its passage a matter of increased mechanical difficulty the vigorous peristaltic waves endeavour to drive the foreign body, together with the

closely applied intestinal wall, downwards. Typical examples are: Impacted gall stones, hair balls, etc. Tumours projecting into the lumen, but attached to the bowel wall, induce colic by the same mechanism, invagination being only prevented by the anchorage of the mesentery, the resulting tension on which produces colicky pain with each similar effort. One of the best illustrations of this is the inversion of Meckel's diverticulum. Some years ago⁷ I showed that not only was this the mechanism of inversion of Meckel's diverticulum, but that intussusception was initiated in a similar manner by the inverted diverticulum itself.

If an attached tumour can so far project into the lumen as to constitute part of the intestinal contents, and be so dealt with by the motor mechanism, then any swelling which projects in a like manner will be liable to the same treatment and cause the same symptoms. The loosely attached and redundant intestinal mucosa is peculiarly liable to hyperaemia, congestion, and swelling under the influence of any irritant—a fact well illustrated by the oedema, swelling, and tenesmus in inflammation of the rectal mucous membrane. Such swelling of the mucous membrane not only projects into, but may even almost close, the lumen of the gut, particularly during the passage of a rhythmic wave; and the resulting effort to drive the swollen mucosa down the lumen, together with the consequent mesenteric traction, produces colicky pain in the same manner.

FIG. 3.—Shows first stage of inversion.

FIG. 4.—Shows inversion completed.

FIG. 5.—Shows mesenteric drag due to inverted diverticulum producing intussusception.

Such a mechanism is responsible for the colic in enteritis due to irritants, worms, violent purgatives, etc., but their character is indicated by diarrhoea or even the passage of blood with mucus. The general, slight, abdominal tenderness and discomfort are due to the hyperaemia of the sensitive mesentery, in whose associated vessels any vascular changes in the intestine are closely followed.

Congestion and swelling of the lymphoid tissue of the intestine is similarly one of the causes of colic, particularly in the lower ileum. It is sometimes accompanied by an acute or subacute enlargement of the associated mesenteric lymphatic glands.

Marked swelling of Peyer's patches may encroach on, or even nearly obliterate, the lumen of the lower ileum, and the peristaltic waves attempt to drive the swelling into and

down the intestinal lumen. The length, rigidity, or elasticity of the attached mesentery is the determining factor in the result; the short, rigid mesentery will prevent inversion or intussusception, but colicky pain is excited with each peristaltic wave; the long, elastic mesentery (common to many infants and young children) provides

insufficient anchorage and intussusception results. The extent of the intussusception varies with the degree of persistence or fusion of the caecal and colic mesentery (that is, the degree of mobility of the colon).

Thus, if dietary indiscretion is associated with lymphatic hypertrophy, engorgement, etc., we should expect that the origin of an intussusception, arising from this cause, would be commonest where lymphoid tissue is most abundant and where there is the greatest delay in the passage of chyme—that is, in the lower ileum. Fitzwilliam⁸ showed by statistics that errors of diet were responsible for a large proportion of cases of intussusception, while it is notorious that the commonest variety is that starting in the lower ileum (where the greatest delay normally occurs). Further, it can be verified by clinical observations that in most ileocolic intussusceptions there is a very marked and rather massive glandular enlargement in the ileo-colic angle. It is logical to infer that intussusceptions of dietary origin are usually ileo-colic, are due to lymphatic hypertrophy and congestion, are rarely recurrent, and are naturally the

commonest variety encountered. Finally, if this deduction is sound, it must be conceded that the mechanisms of intestinal colic and intussusception from this cause are identical, the difference being only a question of degree and anatomical

variation.

(b) Intramural Lesions.

Small primary growths of the small intestine, undetected by palpation, are exceedingly rare (though I have on one occasion encountered a typical ring carcinoma of the lower ileum), so that lesions we are now considering are nearly always inflammatory, and may occur in three ways:

1. Extension from within (for example, tuberculous and typhoid ulceration).
2. Extension from without (for example, from the peritoneum, mesenteric glands, etc.). The character of such lesions is, however, seldom obscure; I only mention them to pass on to the consideration of the third type.
3. Invasion from the blood stream. I am particularly anxious to emphasize the mechanism and character of this type of intestinal colic because, though I have frequently called attention to it during the last seven years,⁹ I am convinced that insufficient consideration is given to it at the bedside. The infective agent (I am using this term in the broadest sense), arriving by the arteries, will be arrested at the narrowest terminal portion of the vessels or in the capillaries—that is, at the antimesenteric border of the bowel—

swelling, congestion, thrombosis, and exudation (and, in severe degrees, haemorrhage) invade the coats of the bowel and prevent musculo and nerve tissue from performing their function. The effect of such a lesion is to render inactive a definite area or definite areas of the intestinal wall. I have termed these "inert areas," and Figs. 6 and 7 show how, in-cisive in themselves, these "inert areas" are responsible for the production of intestinal colic.

The inhibition of function by inflammation or exudation (a feature common to inflammation in any region) renders the inert area of the intestine incapable of ordinary mechanism of contraction and relaxation. On the arrival of a stimulus the latter fails to respond to the inhibitory stimulus, and is therefore forced with the intestinal contents into the lumen of the normally inhibited (and therefore dilated) segment below. (Figs. 6, 7, and 8.) A resulting invagination is prevented by the anchorage of the mesentery (Fig. 8), but the traction exerted on the latter induces pain whose characteristic feature is a complete absence except during peristalsis.

It is not difficult to conceive that small localized lesions (either single or multiple) of this character can and do so interfere with normal peristalsis as to give rise to colic in the manner described. Clinical evidence is not lacking that this is true.

Such an effusion progressing unchecked may not only become palpable but may rupture the mucosa and cause haemorrhage with intestinal colic; it is recognized as "Hemoch's purpura," a sequel of rheumatism. If this is so, we must also concede the possibility that, in a lesser degree, inert areas (either single or multiple), which cannot so be palpated, can similarly produce intestinal colic without any other indication of their presence.

Acute Rheumatism Associated with Intestinal Colic.—The ubiquity and varied character of the lesions associated with acute

rheumatism are well known. Thus we find the varieties of arthritis rheumatica; localized lesions, such as erythema nodosum, and the more chronic rheumatic nodules; ipso-cyclitis, endocarditis, pericarditis, etc., all manifestations

of this ubiquitous general infection. That analogous lesions may occur in the intestine is recognized in the association of rheumatism with Hemoch's purpura; but it is not sufficiently realized that similar lesions of less degree may, though not detected, give rise to intestinal colic.

Intussusception Associated with Acute Rheumatism.—It would be expected that inert areas (whether microscopic or macroscopic) would occasionally be invaginated and intussusception result in the cases where the length and elasticity of the mesentery provided insufficient anchorage to prevent it. Such cases are, in fact, occasionally encountered.

A significant feature in intussusception is that the "dimple" or the first portion to be invaginated is never on the mesenteric border of the gut, but is always antimesenteric, or nearly so. The coincidence of this with the probable situation of an "inert area" still further accentuates the relationship between general infections and intussusceptions. Another feature of this class of intussusception is its ubiquity. Thus, while those of dietary origin are nearly always ileo-colic, those of infective origin are equally likely to be enteric, caecal, or even colic in origin. Of these latter the caecal is, in my experience, the commonest; but I have encountered two colic intussusceptions existing at the same time in one patient, the first starting in the ascending, and the secondary one in the transverse colon. Finally, in the absence of an anatomical reason, an infective origin accounts for the occurrence in more than one member of a family, and for the unexplained instances of recurrent intussusception, of which I have already published an instance where I operated for the third time on the same patient at long intervals.

Insensibility of Intussusception.—In intussusception, as in simple colic, pain and before the onset of peristalsis are conspicuously absent except during peristalsis. The patient often sleeps quietly in the intervals. This feature is not so evident when intestinal distension has supervened; but if, as is believed by some, the intestinal wall itself is sensitive to distension, it is curious that such gross distension of the bowel wall as obtains in the intussusceptions should so far be innocent of any afferent impulses as to permit of peaceful sleep! This, together with the absence of tenderness and cutaneous hyperaesthesia, constitutes strong evidence of the insensibility of the intestinal wall to every form of stimulus.

Other examples of general infections which may similarly cause intestinal colic (and even intussusception) are diphtheria, acute tonsillitis, etc., associated with these infections I have encountered many cases where they are constantly encountered. The clinical feature of importance is the abdominal pain, often with a complete absence of other local signs and symptoms. Amongst urticarias must be mentioned the abdominal pain arising in the course of "serum rheumatism."

It is attributable to inert areas caused by patches of serous effusion into the intestinal wall akin to those seen under the skin. In one instance a caeco-colic intussusception occurred during an attack of acute tonsillitis (supposed "influenza") with catarrh and cervical adenitis.

Localization of Pain in Small Intestine Colic.—Since the mesentery of the viscera is their sense organ, pain is referred primarily to this structure. As, in the case of the stomach, pain is referred to the gastro-hepatic omentum—that is, the epigastrium—so in the small intestine colicky pain is referred vaguely to the middle line—that is, the situation of the small intestine mesentery—and is not associated with cutaneous hyperaesthesia. Inaccuracy of localization is thus a prominent feature of small intestine colic.

LARGE INTESTINE.

Before considering colic in relation to the large intestine, the appendix may with advantage be referred to separately.

Appendix Colic.—The appendix, insensitive itself, is sensitive through its own and the adjacent ileal mesentery; and that the same principles apply is shown by the rare cases of intussusception of the appendix. This rare condition I have twice encountered. In one instance the intussusception started at the tip and involved the distal third; in another the base was invaginated into the caecum and, dragging with it the proximal third, started a caeco-colic intussusception. The rarity of true colic is accounted for by (a) the narrowness of the lumen in proportion to thickness of the wall, and

(b) the poor blood supply. Thus, an intramural lesion is more likely to lead to thrombosis in the mesentery and gangrene of the appendix than to invagination or colic.

FIG. 6.

FIG. 7.—Shows contracting segment of peristaltic wave forcing inert area into lumen of inhibited segment.

FIG. 8.—Shows invaginated inert area producing mesenteric drag and colic or intussusception.

Appendicitis in relation to General Infections.—Intramural infection of the appendix via the blood stream, proved experimentally by Poynton, is a very common event in clinical practice. The resulting lesion (corresponding to the "inert areas" described) tends to produce mesenteric oedema and thrombosis, and pain is localized in the mesentery (the meso-appendix). Every degree of inflammation, from local or general congestion and swelling to gangrene, is met with, the characteristic feature being that the mesentery is always oedematous, friable and thrombosed, and the lumen often shows no abnormality.

In blood infections of the appendix, then, the same "inert areas" lead to a different pathological sequel, and acute or recurrent rheumatism, tonsillitis, and diphtheria, may be mentioned as examples. To these must be added, again, the administration of serum. In some cases treatment of the primary infection suffices to secure permanent immunity from further trouble; in other severer cases appendicectomy is urgently demanded.

Thus, in one case of diphtheria, typical pain and tenderness in the right iliac fossa, associated with vomiting and constipation, made their appearance in the first twenty-four hours, but disappeared completely on the administration of antitoxin; and up to the present time (ten years later) there has been no recurrence. On another occasion I operated on the twelfth day of diphtheria, with cardiac complications, and removed a gangrenous appendix with diffuse spreading peritonitis.

I wish to emphasize the frequency with which recurrent abdominal pain disappears without laparotomy on the removal of a remote source of infection—that is, teeth, tonsils and adenoids, etc.—such treatment removing the origin of recurrent inert areas.

The Colon.

Here the principles are identical, but symptoms differ in detail with the different mechanism. Thus the continuous rhythmic waves are less evident and feebler, except when accentuated by reflex parasympathetic stimulation in three ways:

1. By hunger, smelling or taking food, both of which reflexly excite the vagus over its entire distribution; or

2. By their reflex stimulation from the anus through the lumbar centre (that is, in defaecation); or
3. By the arrival of a fresh load from the ileum, which normally occurs in association with (1).

Either of these three factors so increases the local pressure on the contents of the colon as to excite the pressure stimulus responsible for peristalsis—represented in the large bowel by a "mass movement." Mass movement consists in the vigorous contraction of a whole length or segment of intestine, which forces its contents (along the line of least resistance) into the inhibited segment immediately beyond, when the process is repeated. A whole column of faeces is thus moved from one segment to the next.

I have on one occasion observed a mass movement during laparotomy, and I was profoundly impressed by the extraordinary power exerted by such a thin-walled structure. Not only did the bowel contract into a hard rigid cremated tube about one-third of its former diameter, but by a striking contraction of its longitudinal bands the length of the contracted segment appeared to be so diminished that the long looped transverse colon lay across the transpyloric plane—a hard, firm, cremated tube, clearly capable of obliterating kinks and bends which might be observed during quiescence. The whole process gave one an impression of great power.

Now, except in the presence of obstruction, mesenteric or peritoneal involvement, colicky pain or discomfort arising from lesions of the colon seems mainly in association with the powerful mass movement; it is therefore definitely related to (or accentuated by) taking food and the act of defaecation. The character of the pain is identical with that occurring in the small intestine, since it occurs by reason of the drag on the mesentery (or on the attached peritoneum when mesenteric fusion is complete) produced by the attempted invagination of the inert area.

Localization of Pain—One of the characteristic features of lesions of the colon is the ability of the sufferer to localize the site of the lesion; this is especially noticeable in such definite lesions as carcinoma, in itself a painless disease affecting an insensitive structure. I would emphasize once more that the rectum is excluded from this statement, since in this neighbourhood the gradual resumption of voluntary control over the passage of contents (that is, evacuation) is accompanied by the gradual return of sensibility. The wide area of mesenteric attachment of the large bowel (or of the bowel to the sensitive peritoneum) is responsible for this power of definite localization; for the mesenteric drag induced by the attempted inversion is clearly referred to the mesenteric attachment in the neighbourhood of the lesion. Finally, it is this power of localization which is often responsible for colic, associated with lesions of the colon, being attributed to a gastric origin. This is particularly true of the left transverse colon. For the onset of pain is initiated by mass movement coincident with the taking of food; the reference of the pain to the mesocolon may resemble fairly closely that referred to the gastro-hepatic omentum; and thirdly, the mechanical stimulation of mesenteric nerves in the immediate neighbourhood of the solar plexus evokes a reflex persistence of pyloric closure leading to flatulence and gastric distension.¹⁴ Thus, for example, it is not uncommon for carcinoma of the transverse colon to be mistaken for a gastric lesion.

Lesions of the Colon Associated with Colic.—These are infinitely more numerous than in the case of the small bowel; for not only is the large intestine the home of a variety of organisms (through which a lowered immunity may at any time establish an infective colitis), but the normally slow and interrupted motor mechanism predisposes to delay, and may lead to the formation of solid, scybalous masses which cause colic in the same manner as the gall stone or other foreign body in the small intestine. It is unnecessary to summarize again the types of lesions (whether in the lumen or intramural) once the differences between the small and large bowel have been accentuated, since it is the principle I am anxious to establish—namely, that in both instances the bowel is insensitive, and induces colicky pain through its mesentery or peritoneal attachments.

(c) Inflammation of the Peritoneum.

In the acute stage peritonitis never causes colicky pain, except in those very rare instances where it is coincident with intestinal obstruction. I have on two occasions seen obstruction, with visible peristalsis, associated with acute appendicitis and abscess formation. But this is exceedingly rare, since an inflammatory lesion of the peritoneum stimulates the sympathetic, both efferent and afferent, and ensures thereby an

absolute immobility of the intestine by active inhibition.¹⁵ Peritoneal adhesions may cause colic, but the main clinical feature to be remembered is that inflammation of the mesentery is usually associated with inhibition and intestinal immobility; and that in those cases where colic also occurs there exists also a fairly constant pain or discomfort of smaller degree associated with local tenderness. In other words, a constant pain is aggravated by intestinal movement, in definite contrast to the complete immunity in lesions of the bowel except during peristalsis.

Lesions of the Mesentery.—For practical purposes inflammatory lesions only need be considered, and these may affect the peritoneal surface or be contained within the folds of the mesentery; they may be acute, subacute or chronic. Briefly these may be considered in two groups:

1. Inflammation of the lymphatic glands.
2. Inflammation of the peritoneal surface.

1. Inflammation of mesenteric glands, whether acute or chronic, may be associated with colic which nearly always arises in the small intestine, or the ileo-colic angle. The primary focus in the intestine may itself be responsible for the pain as already described; but the glands themselves may also be responsible. For the inhibitory segment of the peristaltic wave normally exerts a physiological degree of tension on the mesentery during its passage, and, in the presence of inflamed glands, drags on these and causes pain.

2. It has been shown that an irritative lesion of the mesentery provides a constant, if small, stimulus to the contained efferent and afferent nerves; the stimulus to the former results in an active inhibition ("paralysis") of the segment of intestine supplied. The resulting effort to invaginate such an inhibited segment may cause mesenteric traction and pain.

(d) Alteration in Relative Sympathetic and Parasympathetic Activity, and in their Hormone Equilibrium.

The automatic rhythmic contractions of the intestine are accentuated by parasympathetic stimulation, which thus excites the peristaltic wave; the antagonistic nerve supply is the sympathetic, stimulation of which inhibits intestinal movement. Interference with this controlled motor mechanism may arise in two ways:

1. A relative increase of parasympathetic stimulation.
2. A relative increase of sympathetic stimulation.

1. A relative increase of parasympathetic stimulation may again be effected pathologically in two ways—by sympathetic paralysis and by excessive parasympathetic stimulation. The results of both these conditions are the same—namely, irregular and excessive contraction of the intestine, a condition known as enterospasm.

Enterospasm is characterized by the firm contraction or closure of irregular segments of intestine, and the failure of such contracted segments to respond to the inhibitory stimulus of the peristaltic wave. Peristaltic waves arriving at such a "closed" segment endeavour to invaginate it into the lumen of the intestine (as in the case of an organic stricture), and colicky pain results from the mesenteric drag. Enterospasm may be met with in almost any degree, from mild recurring discomfort to acute colic associated with distension, vomiting, and constipation, so severe as to simulate closely intestinal obstruction. In clinical practice the commonest cause of enterospasm is sympathetic paralysis by nicotine (tobacco poisoning); but, though the practical knowledge of hormones is in its infancy, we should be alive to the possibility that these may be important factors in deranging the equilibrium of sympathetic and parasympathetic control. Thus, for example, adrenaline (the hormone of the suprarenal medulla) not only in itself behaves identically with sympathetic nerve stimulation, but lowers the threshold to such stimulation; cholin (and the problematical peristaltic hormone¹⁶), on the other hand, possibly exercises a similar function on the parasympathetic, and would thus be a physiological antagonist.

Though a consideration of the practical aspect of the different hormones would carry us into speculative fields far outside the scope of this paper, I think we ought to remember that, like the vegetative nervous system, the internal secretions of the various endocrine glands, either mutually synergic or antagonistic in function, normally maintain a condition of equilibrium. When these hormones exert a control on the neuro-muscular mechanism of the intestine, any derangement of their normal equilibrium may result in unbalanced stimulation of the intestinal nervous system and be responsible for obscure colic. This is one respect in which sex possibly plays an important part.

That excessive parasympathetic stimulation (or an over-secretion of its respective hormone or hormones) may also be responsible for enterospasm must also be conceded, for in some instances colicky pain may be temporarily relieved by counter-irritation of the skin.

2. *Relative Increase of Sympathetic Stimulation (and of the Suprarenal Hormone).*—Since the function of the sympathetic and its hormone is mainly inhibitory, any relative increase of activity leads to delay or stasis from imperfect intestinal contraction and cannot directly cause colic. But the resulting constipation may lead to the formation of scybalous masses, and the passage of these may be attended with severe colic in the manner described. Retentive colitis from the same cause may similarly be attended with colic. Such a relative increase may be effected in two ways:

(1) *By Over-stimulation of the Sympathetic.*—This subject has elsewhere been dealt with at length in its surgical aspect.¹² I need here only say that, in all probability, sexual functions exert their most important influence on stasis in the colon through the sympathetic and the corresponding hormone; and that into this group should also be classified visceral disorders arising from peritoneal lesions, psychical abnormalities, visceroprosis, dyschiria, etc.

(2) *By Relative Decrease of Parasympathetic Control.*—Into this group may be placed the intestinal distension and constipation associated with paraplegia, where paralysis of the parasympathetic yields unchecked domination to sympathetic or inhibitory impulses. Into this group also I am inclined to place Hirschsprung's disease, in the belief that, as in a large number of congenital deformities, there is a central nervous system defect or lesion. This, I believe, leads to unbalanced inhibition and a local motor failure, which automatically excites progressive overaction and hypertrophy of the proximal bowel. Some years ago I operated on a man twenty years after the radical cure of a low spinal liffida. Here I found a typical Hirschsprung's giant sigmoid, and the close resemblance impressed me with the possibility of a similar origin. But if this is so, it is curious that the one was associated with a similar hypertrophy of the bladder; while, so far as I am aware, this is not a feature of Hirschsprung's disease.

In conclusion, obscure intestinal colic may arise from temporary causes and be of no real significance; its treatment may be medical, or it may constitute a grave warning of an impending surgical crisis.

A full understanding of its significance depends, I am convinced, on an appreciation of the fact that the bowel itself is insensitive; that colicky pain arises from, and is referred to, the mesentery; and that the mechanism of colic consists in the natural attempt of the bowel to drive onwards a diseased or inert area, thereby inducing an abnormal tension on the associated mesentery.

THREE CASES ILLUSTRATING THE VALUE OF PYELOGRAPHY.

[With Special Plate.]

BY

CLIFFORD MORSON, AND H. P. WINSBURY WHITE,
O.B.E., F.R.C.S. F.R.C.S. EDIN.
ST. PETER'S HOSPITAL FOR URINARY DISEASES.

DURING the last thirty years considerable progress has been made in the accurate diagnosis of diseases of the urinary organs. With the advent of the cystoscope in 1885 obscure signs and symptoms due to pathological changes in the kidneys and bladder came to be recognized, and, after further experience, were satisfactorily interpreted.

Following the introduction of this instrument, ureteral catheterization was successfully undertaken, and the segregator consequently fell into disuse. The ability to draw off urine from each kidney by means of a catheter passed up the ureter led investigators to inject fluids, opaque to the x rays, into the renal pelvis, and in 1906 Voelcker and Lichtenberg presented the first paper on pyelography. Since then the literature on this subject has swelled to enormous proportions, and includes profitable dissertations on the evolution of this method of diagnosis, and upon the advantages and disadvantages of different opaque media.

The essential value of pyelography is the reliability with which it determines the presence or absence of disease of the kidneys when the evidence drawn from other sources is insufficient or obscure. Illustrative of this are the details of three cases of hydronephrosis in each of which the diagnosis remained doubtful until the patient had been submitted to pyelography.

CASE I.

J. B., a professional singer, aged 25, had complained of constant dull aching pain in the left loin for three years. His symptoms commenced while in China, and were there diagnosed as a left-sided plicatury. He gave no history of symptoms which could be referred to the bladder until careful questioning led him to acknowledge occasional nocturnal frequency of micturition. Deep palpation of the abdomen in the region of the left loin caused the patient to complain of discomfort, but there was no muscular rigidity.

A skiagram taken of the whole urinary tract showed no shadow of a calculus; cystoscopy demonstrated a normal bladder wall with slight infection of the mucous membrane around the left ureteric orifice.

A specimen of urine was obtained from each kidney by means of ureteral catheterization, 15 grams of urea having been given previously by the mouth. The result of the chemical and bacteriological examinations of the fluid, shown in the following table, is instructive:

Right Kidney.	Left Kidney.
No pus cells.	A few pus cells.
No organisms.	An occasional coliform bacillus, but no growth occurred on culture media.
2 per cent. of urea.	0.65 per cent. urea.

At the same time that urine was drawn off from each kidney to obtain a sufficient quantity for the foregoing examination, pyelography was performed by the injection of a 30 per cent. solution of sodium bromide. The pyelograms showed a normal right kidney and disintegration of the secreting tissue of the left kidney.

At operation a large hydronephrotic kidney was removed through an oblique incision in the left lumbar region. The disease was due to an aberrant artery crossing in front of the ureter at its junction with the pelvis and entering the lower pole of the kidney. (See Special Plate, Fig. 1.)

Recovery was uninterrupted, the wound healing by first intention. The patient on discharge looked remarkably well.

CASE II.

A. C., a clerk aged 29, gave a history of three months' pain in the left loin which was constant and dull in character. A diagnosis of lumbago had been made. At the onset of his illness the patient had noticed slight frequency of micturition, but, apart from this, bladder symptoms had been absent. His appetite was poor and he had lost weight.

An abdominal examination did not elucidate the cause of the pain, as neither kidney could be felt enlarged or tender on palpation. X-ray examination of the urinary tract was negative to the presence of calculus. Cystoscopy revealed a normal bladder with oedema of mucous membrane around the left ureteric orifice.

The bacteriological and chemical reports of the urine from each kidney after the administration of 15 grams of urea by the mouth were as follows:

Right Kidney.	Left Kidney.
No pus cells.	No pus cells.
No organisms.	Plentiful growth of coliform bacilli.
3.4 per cent. urea.	0.6 per cent. urea.

Pyelography of each kidney was carried out by injecting a 30 per cent. solution of sodium bromide through a ureteric catheter. The pyelogram on the right side showed a normal kidney and that on the left side complete destruction of the calyces and distension of the pelvis. (See Figs. 2 and 3, by Dr. Reynolds.)

Operation consisted in left nephrectomy for hydronephrosis due to constriction of the ureter at the retro-pelvic junction. (See Fig. 4.)

The patient made an uninterrupted recovery and was discharged three weeks after the operation, looking and feeling well and having gained weight.

CASE III.

On the recommendation of Dr. Wynnham Gittens, Captain F. P. C., aged 23, consulted one of us for pain in the left loin. He stated that while on active service in Egypt during 1919 and 1921 he had felt slight discomfort in the left loin, and that during his passage home on board ship in July, 1920, he was seized with severe pain in the left loin, referred to the left half of the abdomen. A repetition of the attack took place in August, 1922, about which time he was admitted to a military hospital.

The examination consisted of cystoscopy, investigation of the urine, and skiagraphy. Apparently he was discharged from this hospital without special treatment. He underwent, at a later date, that he was suffering from gout. Since leaving hospital the attacks of pain had become more severe and at shorter intervals, and in

recent months he had been carried off the Rugby football field owing to an attack of pain in the left loin when collared, and even when dancing he was sometimes obliged to retire with similar symptoms.

At examination the right kidney was palpable and enlarged, the left kidney tender on palpation. Micturition was not quite normal, the patient being obliged to pass urine once during the night. The urine was clear and contained no pus, but a streptococcus was grown on culture. Temperature 99°.

Cystoscopy showed the bladder wall to be healthy, with slight injection of the mucous membrane around the left ureteric orifice. Pyelography demonstrated hypertrophy of the right kidney and disorganization of the left kidney. (See Figs. 5 and 6.) In this case the injection fluid used was a 30 per cent. solution of sodium iodide.

A rise of temperature and increase of pain in the left loin followed this examination, which indicated immediate operation. The left kidney was therefore exposed by a lumbar incision; it was found to be so large and tense that an incision had to be made in the capsule to draw off the retained urine and solution of sodium iodide before it could be delivered out of the wound. Nephrectomy was then readily performed. Examination of the specimen after operation revealed an enormously distended pelvis and complete obliteration of the calyces.

Recovery was uneventful, the feeling of fitness so soon after a major operation being again noticeable.

Commentary.

It is a matter of considerable interest that the disease in each of these cases was on the left side. The obstruction in Cases I and II was congenital, an aberrant vessel kinking the ureter in the one and a stricture at the uretero-pelvic junction blocking the other. In the third no cause could be found for the destruction of renal tissue. There was no dilatation of the ureters in any of these cases.

A comparison of the condition of the urine shows how little such an examination, by itself, must be relied on to determine the presence or absence of a gross lesion of the kidney.

Bacilluria was present in all three cases but without pus formation. The urea concentration test was of some assistance in determining the efficiency of the kidneys, but more reliance was placed in the appearance of the pyelograms to assist in estimating their function.

The chronic ill health produced by hydronephrosis in which there is no pus formation, and where the opposite kidney is functioning satisfactorily, is noteworthy. Equally remarkable was the sense of well-being that each patient demonstrated within fourteen days of removal of the diseased organ. This characteristic was not due to an improvement in the metabolism of nitrogenous products, for previous to operation the sound kidney had been proved to be excreting the normal amount of urea consistent with good health, but rather to the removal of an organ which, by virtue of the process of degeneration, is circulating toxins of an unknown chemical nature in the blood.

The pyelograms reproduced on the accompanying plate faithfully represent the normal as well as the abnormal anatomy of the kidneys. Those of the healthy organs show the calyces with their cup-shaped extremities, while those of the hydronephrotic kidneys reveal stunting, or even entire absence.

A further study of pyelography in cases in which the renal cortex is being destroyed will aid in determining the extent of the damage. Thus, in the early stages there is distortion of the calyces, but later the pyelogram shows shadows of globular shape, three to six in number, situated immediately beneath the capsule, and which are adjacent to the large shadow representing the overdistended pelvis. It will be noted in all cases that the shadow of a normal kidney is always more dense than that of a hydronephrosis owing to the dilution of the opaque media by retained urine.

Finally, we give it as our considered opinion that, as a result of the introduction of cystoscopy, ureteral catheterization, and pyelography, no surgeon is justified in performing an exploratory operation upon the kidney. Science has placed in our hands the means of making an accurate diagnosis without recourse to cutting down upon the kidney and inspecting it with the naked eye.

Our thanks are due to Dr. Reynolds and Dr. Salmoud for the pyelograms, and to Mr. Shiells for the drawings.

BARBED wire entanglements guarded by armed men have been set up to isolate the town of Poleau, Heavener, and Wister, Oklahoma, U.S.A., where an epidemic of small-pox is prevailing. According to the *New York Medical Record*, compulsory vaccination is also in force.

A BONE CLIP FOR THE OPERATIVE TREATMENT OF FRACTURES:

END RESULTS IN THE CASE OF GROWING FEMURS.

[With Special Plate.]

BY

JOSEPH E. ADAMS, M.S., F.R.C.S.,

SURGEON, ST. THOMAS'S HOSPITAL, AND EAST LONDON HOSPITAL FOR CHILDREN.

Fashion plays an important part in surgical technique, and surgical fashions come and go; but they go with greater reason than they come. The principle that nearly every simple fracture requires operation because perfect function depends on perfect anatomy, was preached by Sir Arbuthnot Lane. In course of time it came very near to being one of those accepted surgical generalizations which Sir Arbuthnot himself now says are always wrong. To establish a true generalization is harder, far harder, than to devise, and even to popularize, a new surgical procedure. That perfect function is compatible with imperfect anatomy is now accepted in the treatment of fractures. Our object as surgeons is to recover the function of a broken limb, not necessarily to restore its radiographic symmetry. Experience of war injuries, together with the influence of orthopaedic surgeons, has been largely responsible for the revulsion against converting simple into compound fractures by operating on them. But as long as there are house-surgeons not yet fit to be called surgeons, and surgeons whose waking thought is the knife, operations on simple fractures will continue to be done. All this by way of apology, since I may be accused of unnecessary operations.

Of all bones liable to fracture probably the femur gives the greatest trouble to the setter. One of the chief reasons is the strength and bulk of the muscles which surround and are attached to it. Uncontrolled action and spasm of these muscles, even in young children, may prevent reduction under anaesthesia, and the difficulty is directly proportional to the time which elapses between the receipt of the injury and the attempt to secure replacement of the fragments. House-surgeons do not fully recognize that all fractures, simple as well as compound, are acute cases, and that the best results can only be obtained by immediate treatment. Within four hours of the injury a direct pull under anaesthesia will effect reduction in nearly all fractures of the femur, even including those of the upper and lower thirds. The use of an extension table and the direct application of a plaster-of-Paris case to the limb will usually suffice to maintain good position, and in due course a perfect functional result may be looked for. Flexion of the hip or knee may be required in the difficult cases of fracture in the upper and lower ends respectively; but time is of the essence of the contract, and the earlier the house-surgeon gets to work the easier is his task. If his chief prefers it equally good results can be obtained by the present-day modifications of Thomas's splint. That he should fail in certain cases is no discredit unless it is due to unnecessary postponement. That the surgeon should succeed where his house-surgeon fails is not to be expected except in those cases where a correct interpretation of the skiagram shows the way to successful reduction, and experience alone can teach these points. Inevitably, therefore, the question of operative treatment of some fractures will arise, and the bone most frequently calling for open reduction will be the femur, since alignment of the fragments is of such importance. Spiral fractures of the lower third of the tibia also present especial difficulty. Personally I do not operate on any of the common fractures unless two attempts at reduction without open incision have failed.

If there will always be cases needing operation it is surely desirable that the technique should be as simple as possible, and my conception of an internal splint is the simplest appliance which will hold the bony fragments in accurate apposition whilst the limb is immobilized in an external splint. Even if open operation is necessary to effect reduction a splint for the bone may not be required, and this is well exemplified by the common type of supracondylar fracture of the humerus. Open reduction is often necessary, but satisfactory apposition can usually be secured by complete flexion at the elbow-joint.

In May, 1917, I first described a clip made of spring steel, which was made for me by Henry Lewis, of Westmoreland Street, W.1, for the treatment of fractures of long bones.

FIG. 1.—Case 1. Hydronephrosis due to absent artery.

FIG. 2.—Pycnogram of hypertrophied caliculi kidney. Case II (Reynolds).

FIG. 3.—Pycnogram of left hydronephrosis, showing displaced pelvis and flange-shaped shadows under renal capsule. Case II (Reynolds).

FIG. 4.—Case II. Hydroureters due to constipation of ureteral muscles and valve function.

FIG. 5.—Case III. Pycnogram of right kidney, showing hypertrophy (caliculi).

FIG. 6.—Case III. Pycnogram of left kidney, showing destruction of calyces and a lobulated-shaped shadow beneath capsule (Salmond).

taken October 4th.

Fig. 6.—L. N. Sklegram taken three years later.

Fig. 3.—C. H. X ray taken December, 1920.

My object now is to show the late results of this method of treatment, with especial reference to its influence on growth of the bone. The technique of my operation was described in this JOURNAL four years ago.² It has been urged against circular constriction of a bone that it leads to atrophy, and that if such an appliance as the Parham and Martin band is used refracture is liable to occur. There is much truth in

FIG. I.—A, oblique fracture of femur, produced by saw specimen. The lower transverse fracture is held in good position by two clips, one of which is provided with a supporting flange. The second flange embraces both flange and proximal fragment. B shows the introducer, the prongs of which pass through small loops at the end of the clip. This instrument is made with a screw-joint so that the two halves can be taken apart.

this, but the danger can be avoided by the use of a clip which does not encircle more than two-thirds of the circumference of the bone. It may be seen in the accompanying skiagrams (see Special Plate) that subsequent growth of the bone lessens this proportion so that the danger of pressure atrophy is a decreasing one.

The femur cases which I illustrate were selected for operation only after two unsuccessful attempts at reduction had been made in each case, and all the operations were done over three years ago. If I apologize for finding it necessary to operate on them I see no reason to apologize for the operations themselves. The functional results are perfect and the skiagrams show the anatomical results.

Only a brief description of the necessary instruments is required since the accompanying block (Fig. 1) shows the method of application and two types of clip devised for oblique and transverse fractures. For the latter I have devised two clips, one of which has a long flange attached to it, so that it may support both fragments and be grasped by a second clip. In practice, however, I have found that one clip will nearly always suffice, even for a transverse fracture, and absolutely transverse fractures are not very common. The transverse type which most often resists manipulative reduction is that in which the upper fragment overrides the lower one, and here operation may be called for. A single clip will support the lower fragment whilst the external limb splint is applied.

As to the clips themselves, they are made in several sizes, ranging from half an inch to an inch and a half in diameter, the width of the metal band being proportionate to the diameter. Very careful tempering is required to secure the clip against fracture when it is opened for introduction, and this point has received particular attention from the maker. The tension of the spring is also important, since pressure atrophy must be avoided. This is further guaranteed by the

presence of sharp teeth turned in at intervals from the edges of the clip so that there is a small clear space between the bone and the metal. These teeth obviate the need for screws and secure a firm grip on the surface of the bone. The avoidance of screws is important, for thus the medulla of the bone remains unobstructed, and it is well known that screws do actually become loose by atrophy of the bone in which they are embedded. In the absence of sepsis this atrophy has been denied; but any surgeon who has had to remove screws on account of pain, and not for sinus formation, knows that the screw often rotates in its socket under the action of a screwdriver, and the simplest method of removal is to seize the head of the screw and pull it straight out, proving that its bite has ceased to be effective.

The instruments required for my operation are few in number, and the technique followed is the same as that of other methods of internal splintage of bones except that the clip replaces the bone clamp, and, when once the clip is applied, the operation, except for closure of the wound, is at an end. Thus the length of the operation is reduced by one-half. For clearing the periosteal space I know of no better instruments than Lane's curved elevators, and four of these, two at each end of the wound, will expose the bone, and hold the muscles temporarily out of the way. The size of the clip to be selected is important, and for this purpose the diameter of the bone as shown in the skiagram is an accurate guide. To ensure adequate tension the clips are made on the small side, and, in children, a three-quarter inch clip is most frequently used. The clips are stamped with their diameter. In adults the diameter of the bone is usually more than an inch, and an inch and a quarter clip may be required. In subtrochanteric fractures I have used a clip with a diameter of an inch and a half, but always the diameter of the clip should be rather less than that of the bone which is to be secured.

It is obvious that there is an optimum position for the clip so that it may exert pressure along the lines of force which tend to separate the fractured ends. The tension of the spring results in a closing pressure roughly at right angles to the direction of its opening. This must be borne in mind when applying the clip, and it is important to secure this position before the introducer is removed. It is easy to ascertain by trial how far round the bone the instrument should be passed, and then the introducer can be disengaged by a tap on its lateral aspect to free the prongs from the rings of the clip. The clips boiled for the operation should not be touched by the hand, and they can easily be picked up by the prongs of the introducer passed through the rings of the clip. The introducer is made of such a size as to comply with the requirements of aseptic surgery, and not even the gloved hand should go nearer to the wound than the handle of the instruments.

FIG. II.—Showing the operation completed so far as the bone is concerned. Lane's bone elevators are still in position.

The skiagrams, of which I publish a selection (see Special Plate), are all from cases operated upon over three years ago, and the fractures involved the upper third in the case of C. H. and the middle third in the case of L. N. L. N.'s fracture was a very long one and somewhat spiral. The pictures taken shortly after the operation show very good apposition of the fragments, and, what is more interesting still, the late skiagrams show considerable strengthening of the bone in the neighbourhood of the clips. This demonstrates the fact that these clips do not interfere with the growth of the bone, and doubtless as time passes they will lose much of their grip upon the enlarging shaft.

I have also used this method of fixation in fractures of the tibia, where the reduction of the fracture is oftentimes particularly troublesome. Perfect alignment here is essential to avoid permanent lameness, and such injuries are resistant to manipulation owing to the lack of control over the lower fragment. The lower end of the tibia is certainly not an ideal site for a bone clip, since the bone is largely subcutaneous and the clip cannot be buried as it can in other situations. Nevertheless, if the clip occupies a position above the level of the boot it is not likely to cause trouble, and only occasionally have I had to remove one on account of discomfort. If for any reason it is necessary to remove the clip after its duty has been performed the wound must be re-opened and the clip prised from the bone. No surgical instrument that I know of will cut through this spring steel, and to find the loops of the clip and insert the introducer is extremely difficult. This instrument, however, has been made so that it can be taken apart and introduced, one blade at a time, like midwifery forceps.

With regard to compound fractures, it is generally recognized that the use of internal splints should be avoided until sepsis is banished. There are, however, cases where the position obtained by external splintage is so unsatisfactory that some fixation of the bone becomes justifiable, and an apparatus which secures the position of the fragments without penetrating their substance is surely better than wire or plates.

As a matter of fact, I have used this clip in several compound fractures, mildly infected, as is common in civil practice, with the happiest results. In these cases the clip should be removed as soon as there is evidence that a reasonable amount of consolidation has taken place and there is no risk of recurrent deformity.

Description of Skiagrams on Special Plate.

FIG. 1.—C. H., male, aged 5 years. Fracture of femur on September 4th, 1917. Skiagram taken on September 10th, antero-posterior view. Traction failed to reduce the deformity; 3/4 in. shortening.

FIG. 2.—C. H. Clip applied September 14th, 1917. Skiagram taken on September 18th, antero-posterior view. October 8th: Firm union, no shortening; massage started. October 29th: Patient could raise leg in bed and flex knee through 30 degrees; began to walk on crutches and swing leg. November 5th: Walking on leg and bending knee freely.

FIG. 3.—C. H. Skiagram taken December, 1920, antero-posterior view. Both legs 24 1/2 inches in length. Perfect movement of all joints. Small area of thickening to be felt in upper third of thigh.

FIG. 4.—L. N., female, aged 4 years. Oblique fracture of right femur on September 22nd, 1917. Skiagram taken on September 25th, lateral view. Traction failed to reduce the deformity; 1 in. shortening.

FIG. 5.—L. N. Clip applied October 1st, 1917. Skiagram taken on October 4th, lateral view.

FIG. 6.—L. N. Skiagram taken three years later, lateral view. Perfect functional result.

THE RELATION OF THE CURVATURE OF VESSELS AND OF HOLLOW VISCERA TO THEIR INTERNAL PRESSURE.

BY

CRANSTON WALKER, M.D., B.Sc.,

HONORARY PHYSICIAN TO THE GUEST HOSPITAL, DUDLEY, AND TO THE BIRMINGHAM AND MIDLAND SKIN AND URINARY HOSPITAL.

In considering the pressure within hollow viscera and vessels it is constantly overlooked that the curvature of the containing wall influences the pressure within it.

Historic.

The general problem of the equilibrium of a stretched flexible membrane with the pressures on each side of it was solved by Lagrange¹ in his *Mécanique Analytique*, 1788. The subject was developed chiefly by Poisson² in memoirs dated 1812 and 1829. For surfaces of simple curvature the equations connecting pressure, curvature, and tension can be reduced to very simple forms, such as those given below, and their truth can be demonstrated without the use of higher mathematics. Such demonstrations are easily available in mathematical textbooks—for instance, Besant and Ramsey³ and Lamb.⁴ The formulae are also discussed in many textbooks of physics, such as Poynting and J. J. Thomson,⁵ or the more elementary books of Edser⁶ and of Wagstaff.⁶

They are usually quoted in connexion with the surface tension of liquids, since the surface films constitute, almost without complications, material illustrations of mathematical statements. Some further applications have been made in the domain of physical chemistry.

The physical principles are well known to engineers; in estimating the bursting pressures of boilers and steam-pipes the curvature of their surfaces has to be taken into account,⁹ and the formulae are embodied in the British Board of Trade regulations. The principles are still recognizable, though horribly disguised by the British units of measurements, in formulae used by artisans and to be found in "Mechanics' Pocket-books."¹⁰ When sheets, strings, or wires in tension are wound upon cores, or when a turn of rope is tightened round a bollard, the same principles are involved. Allied formulae are used by architects in estimating the stability of arches and domes.

Although they are thus familiar in many branches of science, the formulae and the physical facts which they express appear to be unknown to the majority of medical writers. An exception was the Rev. Samuel Haughton, M.D.,¹¹ who, in his *Animal Mechanics*, 1847, referred to Lagrange's work and applied it to the parturient uterus.

Formulae expressing the Relation between the Curvature of a Stretched Membrane and the Pressure which it Exerts.

For the derivation of these formulae works on mathematics may be consulted: here they are accepted as data.

In a stretched membrane let t (tension) represent the pull on either side of a line of unit length drawn on the surface, in a homogeneous membrane t will be everywhere the same; let p represent the excess of pressure on the concave side of the membrane over that on the convex; and let r and r' represent radii of curvature such that they lie in two planes at right angles to each other whose intersection is normal to the surface. If the C.G.S. system of units is used t will be dynes per centimetre, p will be dynes per square centimetre; and r and r' will be centimetres. Then—

$$p = t \left(\frac{1}{r} + \frac{1}{r'} \right). \quad 1.$$

If the content of the membrane is fluid, p will be everywhere the same.

As the sum $\frac{1}{r} + \frac{1}{r'}$ is independent of the aspect of the planes in which the radii lie (Euler), it is convenient to choose r and r' as radii of the principal curvatures—that is, the curvatures which are maximal or minimal. For the sphere $r = r'$, therefore, the pressure inside a spherical stretched membrane is given by the equation—

$$p = 2 \frac{t}{r}. \quad 2.$$

For the cylinder with straight axis, r' of the curvature parallel to the axis is infinite, and $\frac{1}{r'}$ is zero; therefore the pressure inside a cylindrical stretched membrane is given by the equation—

$$p = \frac{t}{r}. \quad 3.$$

The length of the cylinder does not affect the pressure.

The reciprocal of the radius is a direct measure of the amount of curvature, and the two terms are used synonymously in mathematical works; the equations can therefore be expressed in words simply—the pressure inside a stretched membrane is proportional to its tension and to its curvature, and the influence of curvature as such is emphasized.

Here a protest must be made against the practice, still common among medical people, of using the word tension to designate what is properly termed pressure. For exact definitions of these words reference must be made to the philosophical literature of mechanics; broadly a tension is an internal force which increases with expansion of the material bearing it, and a pressure is one which decreases. To speak of the "tension" of gases, of dissolved bodies, or of pulses is confusion of language and leads to confusion of thought. In the case of the pulse the arterial wall is in tension, the contained blood is under pressure; the pressure is a force directed outwards, the tension is a force directed along the surface of the wall; since the wall is curved there is a resultant force directed inwards; this force balances the pressure of the blood outwards. The wall may be said to "exert" pressure as a result of its tension and curvature. Another common source of confusion must be indicated. The word pressure as used by mathematicians and physicists designates the ratio of a force to an area, real or imaginary. The total force acting on a surface is not a measure of pressure, but the magnitude of the force divided by the

area of the surface is. In such matters we should adhere strictly to the usage of the more basal sciences.

Using these terms in the physical sense, a simple demonstration of the truth of the equations can be given. Consider a stretched spherical membrane hemisected by an imaginary plane, the total force on either side of this circular plane tending to separate the hemispheres is the pressure on the plane multiplied by its area; the total force pulling the hemispheres together is the tension of the membrane on the circumference cut by the plane, and its total amount is the tension per unit length multiplied by the length of the circumference. These opposed forces are in equilibrium.

$$\therefore p \cdot \pi r^2 = t \cdot 2\pi r$$

$$\text{and } p = \frac{2t}{r}.$$

Similar reasoning can be applied to the cylinder.

Static.

Static deductions from the principle are simple.

(a) If in different membranes the tension is the same, the smaller the radii of curvature the greater is the pressure inside the membrane. The pressure inside a spherical membrane is twice that inside a cylindrical of the same radius. For the purpose of medicine it is important to emphasize that the pressure will be different inside viscera whose walls are of the same thickness and at the same tension if they are different in size or shape.

(b) Supposing the pressure to be the same within a number of membranes, the less the curvature of each membrane the greater must be its tension. A cylindrical membrane will have twice the tension of a spherical of the same radius, and a spherical membrane with twice the radius of curvature of another must also have twice the tension.

For instance, the tension of the cornea must be less than that of the sclerotic; where two blood vessels are in immediate communication, so that the blood in them is at the same pressure, the wall of the larger vessel must be in greater tension than that of the smaller.

Where the thickness of the wall is related to its tension the same statements apply to the thickness. For instance, the intercostal arteries as they leave the aorta have the merest fraction of its thickness of wall, although they withstand the same pressure. The same is true of all small branches of large arteries, the thinness of their walls is related to the sharpness of their curvature, by virtue of which small tension can exert large pressure. This feature of the build of vessels is justified, though not accounted for, by physical principles. With this in mind the tenuity of the minute lenticulo-striate arteries becomes less alarming, and the reproach commonly made that they are small branches of a big artery loses significance;¹² the smaller the stenter, to put it paradoxically. Their tragic failure occasionally must be otherwise explained. The comparatively frail glass gauge tube of a boiler is enabled by the sharpness of its curvature to withstand full steam pressure.

The hemispherical end-caps of cylindrical boilers are made only half the thickness of the sides: One end of the arterial system is capped, during rather more than half of each cardiac cycle, by the aortic valves; owing to the three-lobed arrangement this end-cap is more curved than if it were simply hemispherical. This curvature goes some way towards justifying the thinness of the aortic valves to which Dr. Harry Campbell¹³ has drawn attention.

Dynamic.

The dynamics of the subject are less simple. Two purely physical examples will be discussed briefly as introductions to the complex problems which biology presents.

(a) Where the tension of the membranes is not altered by stretching or contraction. This is the case in liquid surface films, whose tension remains constant whatever changes in size or shape the films may undergo. Soap bubbles afford very convenient and almost uncomplicated experimental examples. The pressure within such membranes varies only with their curvature. Of two spherical bubbles, the pressure is greater within the smaller in inverse proportion to its diameter. If the cavities of the bubbles are connected, the smaller will empty itself into and distend the larger. It also follows that the more a bubble is blown up the smaller becomes the pressure inside it, a fact which may be surprising; but anyone who has blown a bulb on a glass tube has experienced the diminution of effort needed as the bulb

increases in size. The pressures exerted by curved liquid surfaces are probably not negligible in the minute mechanics of the living body.

The amount of external work done by the contraction of the membrane when a portion of its contents is discharged is of great theoretical importance. It is measured by the volume discharged multiplied by the pressure; as the pressure varies during the process it is not easy to estimate the work done without recourse to the calculus.

Let V_1 and V_2 be the volumes respectively before and after the discharge of a definite volume of contents, and let the energy lost or work done be W , then

$$W = \int_{V_1}^{V_2} p \cdot dv.$$

$$\text{For the sphere } p = \frac{2t}{\sqrt{\frac{4}{3}\pi} \cdot \sqrt{v}}$$

$$\therefore W = \int_{V_1}^{V_2} \frac{2t}{\sqrt{\frac{4}{3}\pi}} \cdot \sqrt{v}^{-1} \cdot dv$$

$$= \frac{4t}{\sqrt{\frac{4}{3}\pi}} \left(\sqrt{V_2} - \sqrt{V_1} \right)$$

t being constant here.

(b) The case of extensible membranes which obey Hooke's law, that is, equal linear stretchings produce equal additions to the tension; or, tension is proportional to stretch.

Indiarubber may be taken as an example; although it does not follow Hooke's law exactly, its great extensibility is convenient.

Consider a cylindrical membrane which at radius R has no tension and therefore exerts no pressure. Suppose that the membrane is then distended so that the radius is increased by the addition of a variable amount n , then the circumference is increased by $2\pi n$, and this represents a linear stretch of the membrane at right angles to the axis. According to Hooke's law the tension is increased in proportion to the stretch; let $2\pi nK$ represent the tension, where K is a constant; (K multiplied by the original circumference of the cylinder and divided by the area of cross-section of the membrane at right angles to the circumference is Young's Modulus of Elasticity). Then the pressure within the cylinder is

$$p = \frac{2\pi nK}{R_0 + n}$$

Similarly it can be shown that the pressure within a spherical membrane is

$$p = \frac{4\pi nK}{R_0 + n}$$

Rewriting these equations—

$$\frac{p}{2\pi K} = \frac{n}{R_0 + n} \quad \text{and} \quad \frac{p}{4\pi K} = \frac{n}{R_0 + n} \quad \text{respectively,}$$

it is obvious that while n is small compared with R_0 , the pressure will rise rapidly as n increases, but that when n becomes large the less does further increase of n augment the pressure,

$$\left(\frac{dp}{dn} = \frac{R_0}{(R_0 + n)^2} \right)$$

and that the pressure approaches a limit as the fraction $\frac{n}{R_0 + n}$ approaches unity in value. The two apparently contradictory statements—that the rise in pressure is very nearly proportional to the increase in radius, and that the pressure remains very nearly constant in spite of variation in the radius—are both true. The first statement is true of a membrane slightly stretched, the second of one greatly stretched.

The work done during a discharge of contents can be calculated in the same way as for a surface film, but the resulting expression is rather cumbersome. The relation of the pressure to the varying thickness of the wall also can be expressed, but no advantage is gained.

It is easily deducible from the equations that a cylindrical membrane with fluid contents tends to become the same diameter throughout its length, and that if the cavities of two similar spherical membranes are connected they will become the same size. This is in contrast with liquid films, where the smaller sphere dilates the larger, and the cylinder is unstable when its length exceeds its circumference. The force directed towards uniformity of size becomes smaller with greater dilatation, so that when a membrane is greatly distended small interfering factors can produce marked irregularities in size and shape.

Experimenting with rubber it is not difficult to record rough agreement with theory, but precisely regular results are difficult to obtain. This is due to several disturbing agents, such as departure from Hooke's law, and the fact that in stretched rubber, as in many other materials, the tension diminishes with time, and at a rate which bears no simple relation to other conditions.

Application to Physiology.

The complex problems presented by the dynamics of curved muscular sheets will not be attempted here; it is intended to leave unobserved certain physical principles which must be included, explicitly or implicitly, in any exact consideration of the subject. A few notes only are added further to clear the ground.

It is frequently assumed that all solids follow Hooke's law sufficiently nearly for any practical purpose. I have made a long series of experiments on animal tissues and have found that they all deviate sensibly from Hooke's law, and that many deviate widely. Nor would a definition of "solids" which excluded animal tissues set the matter right. Hooke's law can only be assumed in physiology as a means to a first approximation.

The heart is the most interesting field for the application of these principles, but the bladder is more suitable. The left ventricle is usually said to contain about 100 c.cm. of blood at the beginning of systole, and to discharge about 60 c.cm. during its contraction; if it were spherical its internal radius would be roughly 2.9 cm. at the beginning of systole, and 2.1 cm. at the end. The radius of the bladder is subject to immensely greater variations. The bladder is also thin-walled, nearly spherical, and its pressure is more easily determined than that of the heart.

Everyday experience provides data of considerable interest. Other things being equal, the trajectory of a stream of liquid projected into free air varies with the velocity of outflow, and the velocity is proportional to the square root of the pressure at the opening of the reservoir. After the beginning of micturition, and independently of the abdominal musculature, the trajectory remains nearly constant for some time, and then shortens towards the end, showing that for the first half or so of micturition the pressure in the bladder is nearly constant. Tension and radius must decrease together, although the muscular wall is thickening as the bladder contracts, and it might therefore be expected to exert greater pressure.

Summary.

1. The pressure exerted by any structure comparable to a stretched membrane is dependent on its curvature.
2. The pressure within a cylindrical and a spherical membrane is $\frac{t}{r}$ and $\frac{2t}{r}$ respectively, where r is the radius of curvature and t is the tension.
3. With rubber-like materials, as a curved membrane is progressively distended, the pressure rises rapidly at first, then more and more slowly as it approaches a limiting value.
4. Such materials are only a rough guide to the behaviour of membranes made of muscle and other animal materials.
5. In any exact consideration of the mechanics of vessels and of hollow viscera the curvature of the wall must be taken into account.
6. When such allowance is made, purely physiological effects will be more clearly visible.

Note.—Since the above was written Dr. J. R. Gillespie of Belfast has pointed out the application of these principles in the study of the capillary circulation (BRITISH MEDICAL JOURNAL, 1921, vol. i, p. 873).

ACCORDING to the *Castilla Médica* a State regulation is now in force in Spain by which vaccination against typhoid fever is compulsory, when typhoid or paratyphoid fever are prevailing in epidemic form, for all persons attending cases or in relation with the sick, directly or indirectly.

FOCAL INFECTION IN RELATION TO THE ETIOLOGY OF SKIN DISEASES.*

BY

H. LESLIE-ROBERTS, M.D.,

LECTURER IN DERMATOLOGY, UNIVERSITY OF LIVERPOOL; CONSULTING
DERMATOLOGIST TO THE LIVERPOOL ROYAL INFIRMARY.

THE term "focal infection" may be understood in three senses: First, it may imply that living and virulent bacteria are carried by the blood stream to near or remote organs; there to set up active infection; secondly, that foci such as the tonsils or dental alveoli may act as carriers of bacteria which, harmless to the person who carries them, may by contact affect other persons; thirdly, we may understand by focal infection a collection of bacteria in a crypt, pocket, tube, or fold of tissue, which, while not actively growing or multiplying, may infect the body by their cell substance which is liberated by the action of ferments or enzymes, either by self-digestion (autolysis) or by the enzymes of the cells of the invaded tissue (heterolysis).

With the first two of these aspects of focal infection I am not at present concerned. The third aspect may be conveniently designated by the term introduced by Adams—namely, *subinfection*. Now, since the chief ingredient in the bacterial cell substance is some protein body, we might more accurately name the subject of this present discussion protein poisoning in relation to cutaneous diseases.

It will help to throw some light on this obscure subject if we start with the statement of a fundamental biological fact—namely, that terrestrial vertebrates and bacteria have entered into a symbiosis, in which for the return of food maintenance the enzymes of the bacteria are thrown into line with the enzymes of the body in the scheme of defence against foreign proteins. Our food consists of foreign proteins, carbohydrates, and fats, and it is essential for the welfare of the body that these should not be allowed to pass through the wall of the intestines into the interior without first being deprived of their toxicity. There exists in the body an organized system of defence against foreign proteins. The first line is taken by the cells of the mucosa of the stomach and the higher intestines, the second line by the bacteria of the colon, and the third line by the free moving cells of the lymphoid tissues. As regards the distribution of bacteria throughout the body we find the major portion of them in lymphoid tissue in parts to which food has access. But they are not wholly confined to the surfaces of the body, for it has been demonstrated that no organ is absolutely sterile, but only potentially so.

The flora of the mouth and tonsils is restricted; it consists chiefly of the haemolytic and non-haemolytic streptococci and the staphylococci. The pneumococcus, which is closely related to *Streptococcus viridans*, is a fairly constant inhabitant of the mouth and tonsils. Occasionally more virulent organisms are found, such as the *Streptococcus mucosa* and the meningococcus. Special pathogenic organisms such as the diphtheria bacillus do not form a part of the normal colonies of the mouth and tonsils. Nor does the colon bacillus, for this bacterium is not adapted to growth in the tonsils or mouth; if implanted experimentally in the tonsil it apparently dies out. In addition to the bacterial flora the endamoeba appears to be a constant denizen of the tonsils and alveoli. All human tonsils from a few hours after birth to the end of life are infected with these bacteria; they are not distributed through the lymphoid tissue, but are confined to the crypts and follicles.

The benign physiological action of the tonsillar and alveolar bacteria is digestive and, probably, in no way essentially differs from bacterial digestion in the colon. This will become more apparent if we study the normal relation of the tonsils. After partaking of food, some undigested food particles, often in a state of fine division owing to the soft nature of the modern human diet, find access to the dental troughs and the tonsillar crypts. Milk, cheese, vegetable debris mingled with saliva, salivary corpuscles and mucus collect in the follicles, forming the so-called "cheesy" matter familiar to all laryngologists. In this way tubercle bacilli are introduced; indeed milk may be considered the customary vehicle for this organism. These are attacked by the oral and tonsillar bacteria, and their complex proteins are reduced by

* Paper read at the first meeting of the British Association of Dermatology and Syphilology.

enzyme action to smaller molecular groups, one being poisonous and the others non-poisonous. In short, the follicles of the tonsil may be regarded as accessory organs to the colon by which food remains are digested and disintegrated. The net result of this is the liberation of the protein contents of the cells, both of the food and of the bacteria. But in this digestive process the lymph cells play a major part: they are attracted to the follicles in search of food and thereby their enzymes split up the proteins both of the bacteria and the food cells.

If we examine microscopically the tonsils which the laryngologist usually terms "septic" we find that they do not show the clinical or microscopical picture associated with active infection. The crypts are distended with the so-called cheesy material, and in some cases "pus," or what is commonly called pus, is seen to exude on pressure. But these signs are not accompanied by any subjective or inflammatory symptoms. The patient is quite unaware that anything is wrong with his tonsils.

Microscopical sections of "septic tonsils," taken from a case of chronic alopecia areata, were submitted. In the section of the one tonsil the familiar appearance of the crypts lined by stratified epithelium and surrounded by the lymphoid tissue was to be observed. In the crypt itself was a collection of lymph cells, which could be seen as if passing from the lymph nodes through the epithelium into the crypt. Between the cells were diplococcal bacteria, but nothing resembling the chain form of the streptococci. The diplococcal form has been shown by Adami and others to be a resting form of the colon bacillus and of the streptococci. From this actual tonsil streptococci were cultured. In a section taken from the opposite tonsil of the same case the very remarkable fact was to be noted that the stratified epithelium lining the crypts had been replaced by columnar epithelium.

What is the meaning of this appearance? We are all familiar with epithelial metaplasia, as, for example, when the normal ciliated epithelium of the trachea is replaced by stratified epithelium in the position of the cartilage rings, but I am unaware of any record of squamous epithelium being converted into this columnar form. The structure of this particular tonsil, as represented in this section, is identical in all essential points with the structure of the vermiform appendix. In the latter organ, starting from the cavity, we have the columnar epithelium, the mucosa with the lymphoid follicles, the submucosa, the two muscular coats, longitudinal and transverse, and the fibrous capsule outside. The muscular tissue is absent from the tonsil, but its place is taken by the muscles of deglutition, which compress the tonsils in the act of swallowing. As in the tonsil, lymph cells pass from the lymph nodes through the epithelium into the cavity of the appendix.

Another point of similarity between the tonsils and the caecal appendix is found in their rich vascular and lymphatic supply, apparently out of all proportion to the size of the organ. This rich vascular supply may be taken as evidence of the high rate of metabolism in the tonsils and appendix and of the free interchange of material between the blood plasma and the lymph cells. Regarded in this light the appendix may be said to be the tonsil of the great bowel; nor is there anything far-fetched in this comparison. Kelly of Baltimore, in his classical treatise on the vermiform appendix, expresses the belief that there is a near relation between the tonsils and appendix as regards function, and his view is supported by other observers.

The first section shows the existence of fibrosis, and I specially desire to draw your attention to this pathological change as evidence of protein poisoning. Fibrosis as a result of subinfection has been demonstrated by Adami and Opie in gin-drinkers' liver, or chronic hepatic cirrhosis. The cirrhosis is not the result of the action of the alcohol on the liver cells, but depends on the presence in the hepatic tissues of the colon bacilli. As in the tonsil, there is no evidence of active inflammation or of active growth and multiplication of bacteria. The process of fibrosis, both in the liver and in the tonsil, is a local reaction to protein poisoning in which the physiologically active cells are slowly replaced by fibrous tissue. I would submit to the consideration of laryngologists that fibrosis in the tonsil is a more reliable indication for tonsillectomy than the presence of cheesy matter in the crypt. I have placed under the microscope a section of the appendix taken from a case suffering from erythema nodosum. It will be seen to show all the signs of chronic subinfection with advanced fibrosis. The lumen of the appendix is almost entirely obliterated by the growth of

fibrous tissue and fat cells, while the mucosa has almost entirely disappeared. The tonsils in this case showed marked signs of stasis, with cheesy material in the crypts. They were regarded by Mr. Guthrie, who examined them, as probable sources of focal poisoning, and their enucleation was advised. The general clinical symptoms of the case pointed to chronic protein poisoning, but owing to the long history of appendix trouble it was thought desirable that the appendix should be first removed.

Clinical evidence shows that in the great majority of persons bacterial digestion in the tonsils and mouth promotes only local reactions, and is not accompanied by general and remote consequences, but in not a few individuals symptoms arise which we must attribute to protein poisoning. The experimental parenteral introduction of foreign proteins into animals has shown that the complete protein molecule is a violent poison. Its first introduction into a perfectly normal animal may be followed, if the dose be sublethal, by no very remarkable symptoms, but the second injection of the same protein after an interval of some eight days provokes violent symptoms which may end fatally in a few minutes.

It is not necessary that we should follow the biochemists in their efforts to explain the chemical reactions which follow the entrance of the complete protein molecule into the blood stream and tissues. It will suffice to state the general underlying principle as given by Vaughan, that the foreign protein in the blood evokes the development of an unusual digestive ferment in the cells of the body, and when the mechanism of this heterotopic digestion is once formed, the cell henceforth is sensitized to the particular foreign protein which evoked the proteolytic function. All foreign proteins, whether they be animal, plant, or bacterial, are sensitizers. Bacterial vaccines are protein sensitizers.

To this state of protein sensitization Richet gave the name of Anaphylaxis; von Pirquet proposed the name "Allergy," which etymologically means "altered reactivity." Pathological symptoms accompany this sensitization; the blood-forming organs are specially affected, and anaemia, leucopenia, and eosinophilia appear. The non-striped involuntary muscles are highly sensitive to the protein infection; this is indicated by spasm of the venules and vaso-dilatation, accompanied by the clinical picture of urticaria, flushing of the face, oedema, and erythrodermia. In other cases the sensitization may affect the fibrous tissues, the aponeuroses, the synovial membrane of the joints, producing various forms of arthropathy. When the skin cells are sensitized in cases of chronic allergy various symptoms arise—loss of hair, either diffuse or in area, forms one of the commonest; also increased pigmentation and increased fat formation; in short, we have evident signs of stasis in the cutaneous tissues. Other clinical forms of disease are lupus erythematosus, lichen planus, and prurigo. These we may regard as different clinical pictures, varying according to the particular group of cells which are sensitized. All these cutaneous diseases have been shown by Barber, Whitfield, and Leslie-Roberts to disappear spontaneously after tonsillectomy. A very remarkable case, which has only recently come under my observation, is that of a married woman, aged 34, with a pale, sallow complexion, who had suffered from lichen of the planus type for five months; the eruption was scattered over the wrist, the forearm, and the abdomen in the region of the waist. I found the alveoli in a state of advanced pyorrhea, and sent her to a leading dental surgeon, who advised the extraction of all her teeth. This was done, and twenty days after the operation the eruption had entirely disappeared, with the exception of a minute trace on the right wrist. No external treatment had been used, except a soothing lotion, and no vaccines had been given.

In respect of the erythematous group of reactions I think there can be no doubt that erythema multiforme and erythema nodosum are connected with protein sensitization, but the fleeting character of these reactions, as contrasted with the chronic persistent character of the four dermatoses mentioned above, points to some difference in the mechanism.

With regard to diseases belonging to the dermatitis herpetiformis group I think they can be provisionally at least, included under the head of protein poisoning. I can recall the case of a lady I saw in consultation with a doctor, suffering from severe dermatitis herpetiformis, who recovered under the use of autogenous streptococcal vaccines.

Attempts are being made to include the eczematous reactions under the head of protein sensitization. There are some eczematoid vesicular reactions which I believe are

connected with the state of allergy, but what we may describe as the normal eczematous reactions are essentially related to physical conditions in the external environment. These cases—and they make up the vast majority of eczematous patients—are sensitized to friction owing to a defect in the physical conditions of the rete and cuticle with inherited or acquired increased permeability of the capillary walls. Such cases can be cured by simply raising the pressure of the rete and cuticle over the capillaries.

Exact knowledge is needed, and when this comes we shall be better placed for classifying the protein sensitization diseases. I am not yet prepared to say what value is to be attached to local signs of cell irritability provoked by the intra-epidermic applications of various proteins. There are many conditions which affect cell irritability besides protein sensitization, and for myself I prefer to wait for further evidence.

BILE SALT AS A VEHICLE FOR A PEDICULICIDE.

BY

B. A. PETERS, M.D., B.Ch., D.P.H.CANTAB.,

SENIOR MEDICAL OFFICER, HAM GREEN HOSPITAL AND SANATORIUM,
BRISTOL; LECTURER IN FEVERS, UNIVERSITY OF BRISTOL.

For several years we have been experimenting with various substances for the destruction of head lice, but nothing was found which prevented the hatching out of the nits. It was considered that as bile salts are stated to assist the passage of emulsions of fats through the mucous membranes by their property of reducing surface tension, they might have the same effect in assisting oily emulsions to penetrate the shell of the louse's egg. Experiments were made with various strengths of sodium taurocholate in watery solution with eucalyptus and sassafras oils. The best compound was found to be

Sodium taurocholate	10 grams.
Ol. eucalypti	50 c.cm.
Water	to 1,000 c.cm.

Dissolve the bile salt completely in water, add the eucalyptus oil, and shake well.

A higher concentration of bile salt rendered the hair very sticky, whilst a lower did not form so good an emulsion. More than 5 per cent. eucalyptus rapidly separated out. The formula yields an emulsion like milk in appearance, and but little of the oil separates out after several days.

Most lice, if immersed in the liquid, cease movements in a few seconds, but a few individuals did not die for three minutes. In no case did any of those tested recover when dried on blotting paper and incubated. Larger insects, such as wasps, house-flies, and fleas, when dropped in the emulsion became wetted all over immediately, and died in less than a minute.

During the past eighteen months the emulsion has been tried on over 500 patients on whose heads living lice were seen. It is well rubbed into the head until all the hair is wetted. The head is then wrapped in a bathing cap or towel and the application left on all night. The head is washed with soap and water next morning, and a fine-toothed comb used daily for a fortnight, notes being kept of any lice found. In 23 per cent. of the cases no lice were found after one application. In the remainder a few recently hatched very small forms were discovered, in no case before four days after the first application, in most cases not until after a week, and in a few not until the tenth day. A second application on this reappearance sterilized 63 per cent., while 14 per cent. required a third application.

It appeared that the embryos on the point of emergence were killed, whilst the most recently deposited eggs were more resistant.

Some of the worst infested heads, in which the towel swathing the head was nearly black with dead lice on the morning after the first application, were sterilized with one application, while some of the lightly infected required three applications, so that it would seem that there must be different powers of resistance in certain strains of lice.

This preparation is not toxic, is not irritating to the skin, is not inflammable, and is elegant to use as it is easily washed out of the hair. The cost of the ingredients works out at 6d. a pint.

Possibly the property of bile salt solutions to wet the lice and their eggs can be combined with some substance more poisonous than eucalyptus oil to the louse's egg, so that one application would always be sufficient.

The Lettsomian Lectures

ON

AMOEBIC LIVER ABSCESS.*

DELIVERED BEFORE THE MEDICAL SOCIETY OF LONDON

BY

SIR LEONARD ROGERS, C.I.E., M.D., F.R.S.

[Abstract.]

LECTURE II.—VARIETIES AND TREATMENT.

THE lecturer continued his remarks on pathology by referring to suppurative cholangitis, a rare disease in which he had been greatly interested ever since he met with three cases at St. Mary's Hospital in his third year studentship. Fourteen years later he recorded a case which he had diagnosed and operated on at Calcutta European General Hospital, in which a mass of gall stones was removed from the hepatic ducts. Unfortunately, this case was taken in hand too late, and the suppuration tracked out and opened into a bronchus, with a fatal result. The rarity of this complication in India was explained by the fact that, although gall stones were nearly as common in India as in Europe, in the eastern country most of them were of the soft pigmented variety, and the hard, disease-producing cholesterol form was comparatively infrequent, at least in Calcutta. Suppurative cholangitis would, therefore, seldom give rise to difficulties in differentiation from liver abscess in the tropics. He also spoke of diffuse suppurative hepatitis produced by *B. coli communis*. He had seen this condition in a Calcutta hospital, the patient having leucocytosis with over 90 per cent. of polymuclear leucocytes. He showed a colour drawing to illustrate the condition found *post mortem*, indicating a large diffuse suppuration throughout that half of the liver which was supplied by the right branch of the portal vein, in which an extensive clotting was present, while the remaining half of the organ was healthy.

Frequency of Large Single Abscess.

In his previous lecture he had shown that multiple small amoebic abscesses were nearly always overshadowed by the acute sloughing dysentery to which they were secondary, so that they could not easily be recognized during life, still less easily treated surgically. This variety might therefore be put on one side, and they could turn with more hopefulness to the comparatively chronic, large, fibrous-walled form, and see what lessons the *post-mortem* room and the laboratory could teach them in dealing with this formerly very common and very fatal tropical liver disease.

He gave some statistics which appeared to indicate—it was not a matter for precision—that in about 70 per cent. of cases of large liver abscess the abscess was single. Among 38 cases in which there was found to be more than one abscess there were two abscesses in 44.7 per cent., three in 26.3 per cent., four in 18.4 per cent., and over four in 10.6 per cent. In this connexion he drew attention to the practical importance of the fibrous limiting wall in large amoebic abscess which he had described on the previous occasion. In friendly discussions with surgical colleagues he had often been told that the high mortality of the open operation was due to the amount of destruction of the liver tissue. This he was convinced was not the case. He showed a coloured drawing of a liver with three medium-sized amoebic abscesses side by side, with only about one-third of an inch separating one from another, and said that it might be a matter for wonder that in such a delicate organ as the liver they did not coalesce into one; but on cutting sections it was found that each abscess was limited by a dense fibrous wall, and that the liver tissue in between was perfectly healthy. Once the fibrous wall was formed there was no further destruction of liver tissue, at least as long as the cavity remained free from bacterial infection. He had twice seen six pints of pus aspirated from the liver at a single drainage, and yet a complete recovery took place. If such amounts of pus did not destroy enough liver tissue to cause death he would like to know what basis the surgeons had for attributing the mortality in open operation to destruction of tissue.

Secondary Bacterial Infection after Open Operation.

The lecturer went on to speak of the importance of secondary bacterial infection after open operation on large

* An abstract of the first lecture appeared in the BRITISH MEDICAL JOURNAL of February 11th, 1922, at p. 224.

amoebic abscesses. Tropical liver abscesses were often sterile as regards bacteria, although this important fact had not until recently influenced treatment. After the opening, however, a secondary bacterial infection was almost inevitable. During the daily dressings air was sucked in and out, so that secondary infection might readily be expected in such a climate as India, quite apart from the dangers of copious discharges soaking through the dressings. It was necessary to lay stress upon these unfortunate secondary infections because he had met with surgeons in India who denied their importance, although, on the other hand, many surgeons had readily acknowledged it, and here he quoted Major G. C. Spencer, when Professor of Military Medicine at the Royal Army Medical College, who wrote:

The chief cause of this high mortality, apart from the presence of more than one abscess, or extreme debility of the patient before operation, is undoubtedly infection of the abscess cavity by pyogenic organisms through the open wound. This is extremely difficult to prevent, no matter how much care is taken; the large amount of viscid discharge necessitates frequent changes of dressings, air and pus are sucked in and out of the cavity by respiratory movements, and it is very difficult to keep the skin around the wound aseptic, especially in a hot, moist climate. The great majority of amoebic abscesses are sterile when first opened, and every surgeon with Indian experience is familiar with the usual course of fatal cases—the patient does well for the first few days after operation, then infection occurs, the temperature goes up again, and death from septic poisoning slowly but surely follows.

If such was the experience of a distinguished army surgeon who had had to do with cases under the most favourable conditions, and early cases at that, what was likely to happen in hospitals and dispensaries where advanced cases were dealt with, and the patients came in already greatly debilitated? Enough had been said to prove that any simple method of preventing these deplorable results would be worthy of serious consideration. Such facts furnished a complete scientific basis for a much simpler and more promising method, which, together with appropriate medicinal measures, solved the problem of treatment.

Treatment by Repeated Aspiration and Injections.

Many years ago, before the present views of the etiology of tropical liver abscess were established, all abscesses were naturally looked upon as ordinary collections of pus which should be opened and drained as early as possible. There was, however, one exception: tuberculous abscesses had been treated by aspiration through sound tissues, with or without the injection of some antiseptic substance, because it was recognized that the opening of large tuberculous abscesses connected with bone diseases was often followed by secondary infections. As soon as he was able to establish that amoebae were constantly present in the walls of tropical liver abscesses, and that such abscesses were usually sterile as regards bacteria, he realized that they did not require necessarily the same treatment as abscesses due to pyogenic organisms. Accordingly he began to look for some chemical agent which might be injected into such abscesses. As early as 1902 he reported on the effects of solutions of quinine in destroying amoebae in the wall of an abscess *in vitro*. Clinically, he found that to wash out the cavities of recently opened liver abscesses with a 1 in 500 quinine solution did in fact cause a decrease in the active amoebae present, and that eventually the pus changed almost into a serous fluid. In his advocacy of repeated aspirations and injections of quinine solutions, however, he met with difficulties, because hospital surgeons were unwilling to try the method. The objection generally raised was that aspiration was not a surgical procedure, and his reply that he had never met with a patient who complained of being cured by what was not a surgical procedure was not very cordially received. But, as a matter of fact, before the days of antiseptic surgery in India, the method of repeated aspiration was commonly employed. It was only the progress of antiseptics which led to more frequent resort to open operation.

The first attempt to use his method was made in 1902 by a private medical practitioner, whose repeated punctures, however, failed to strike the abscess, which was evidently on the under surface of the liver, as was proved subsequently when it burst into the stomach. Not until 1906 was he able to record two successful cases. The first case was an acute one, diagnosed by leucocytosis with low polymuclear count, and by x-ray examination; 10 oz. of typical pus were aspirated through an intercostal space, and the temperature reached normal in two days, the leucocytosis disappeared in six days, the patient got up on the seventh day, and left hospital after twelve days. The second case was of a more chronic type, and was equally successful. After

this he had less difficulty in getting his method tested, and in 1910 he recorded 19 cases with only three deaths, or 15.8 per cent., only about one-fourth of the mortality of open operation, and this although many of these 19 cases were of the most serious type. In a series of cases treated by Lieut.-Colonel Thurston by this plan of repeated aspirations and injection of amoeba-destroying drugs, the mortality was only 23 per cent. The number of aspirations which Thurston found necessary was one only in 26 cases, two in 16 cases, three in 10 cases, and four, seven, and eight in three other cases. Two patients recovered after 182 and 211 oz. had been withdrawn by three and by eight aspirations respectively, while in one fatal case 343 oz. were evacuated in seven punctures, including 923 oz. at one sitting.

The reason why aspiration in earlier years—before antiseptic surgery came in—was tried and abandoned was because it was relied upon alone. It was the combined treatment which accounted for success: repeated aspirations, destruction of the amoebae in the abscess wall by appropriate drugs, and the clearing up of the bowel by suitable after-treatment. He gave up quinine after discovering the greater value of emetine hydrochloride in amoebic disease, but before making this change he had many cases of remarkable success.

One case was a European patient who had been operated on by the open method four times in as many months, and was still suffering from high fever and pain after the last operation, so that he had given up hope for himself, and, fortunately for him, the surgeon had given up hope also. Accordingly another line of treatment was tried; large doses of ipecacuanha were given, and the extensive wounds were washed out with quinine solution through the drainage tubes with which his side fairly bristled. Within three days the temperature fell to normal, the amount of discharge rapidly diminished, and the wounds soundly healed. He remained in good health, and resumed his work as a mining engineer in the tropics.

Sterile Siphon Drainage.

While the lecturer submitted that his method of repeated aspiration, combined with specific medical treatment, was the method of election, he agreed that in exceptional cases another procedure might be desirable. Even in those exceptional cases in which drainage was found necessary, however, after one or two preliminary aspirations, both the size of the cavity and the amount of discharge would be less than if the abscess had been opened immediately, so that nothing was lost and much might be gained by evacuation of the pus.

In one case at the first aspiration 86 oz. of typical pus were removed, quinine solution was injected and ipecacuanha given orally. Within a week this patient died unexpectedly, and the post-mortem examination revealed apical pneumonia, quite unconnected with the liver trouble. On examining the liver abscess cavity it was found to have so contracted as to contain only 2½ oz. of thin fluid, and its fibrous wall measured almost half an inch in thickness.

He had records of complete recovery after 120 oz. had been aspirated at a single sitting. One case was that of an emaciated Indian, who had been ill for a year and who made a perfect recovery after a single aspiration and injection of quinine solution into the cavity, and the administration of ipecacuanha orally.

The lecturer then described a method of drainage which he had worked out so that when this measure was necessary no air could enter the abscess cavity and secondary infection might be prevented. He exhibited a trocar with a flexible sheath (made for him by Down Brothers) which was left in the abscess as a drainage tube, and could be connected by a long tube to a vessel containing an antiseptic lotion. With increasing success with the aspiration and emetine treatment, however, this method of sterile siphon drainage was of comparatively less importance. At the same time it had advantages, especially in bringing about rapid healing.

He instanced a case of liver abscess treated by siphon drainage in which a preliminary aspiration of about ten ounces of pus was made through an intercostal space, and siphon drainage applied by means of a tube, the distal end of which was carried into a bottle containing antiseptic. The pus obtained at the operation proved to be sterile. At the end of the first day a few ounces of pus had drained into the bottle, the discharge was much less on the second day, and on the third morning only a little more pus had drained away, and the cavity had contracted so much that the quinine injection could hardly be got in. Within a week the sinuses were soundly healed and the patient left hospital a year later the liver was still quite normal. The size of this patient in hospital was less than half the size of any liver abscess in which operation had been carried out by incision through the thoracic wall.

Nature's Methods of Healing.

Nature's methods of cure of amoebic liver abscess were twofold: bursting of the abscess and encystment. The abscess might increase in size until it burst in one or other

direction. In some cases this resulted in recovery without surgical interference, as when it burst into the stomach or colon; the common extension through the diaphragm into the bronchus showed a recovery rate of over 50 per cent. Cases of rupture into the peritoneal cavity were commonly fatal. The other method of Nature's healing was by encystment, with dying out of the amoebic infection. This was less uncommon than might be expected. There were seven instances among the Calcutta *post-mortem* records of cases dying with other diseases in which this state of affairs had been found. In one instance he found an abscess which had been opened and drained during life containing both amoebae and bacteria, a second containing amoebae only, and a third encysted, without either organism. The liver abscess became encysted with emetine treatment, and he claimed that his method of repeated aspiration and injection aided this effort at encystment of the abscess by destroying the protozoal parasite in the walls and by removing the detritus. The method was, therefore, as sound in principle as it had proved to be successful in practice. The danger of haemorrhage after exploratory puncture had often been remarked, but it appeared that the greatest tendency to fatal haemorrhage was in the acute hepatic congestion of the pre-suppurative stage of the disease, and therefore such a puncture should not be done in any case in which liver abscess was suspected without first treating the patient by medicinal means to which the hepatitis at this stage was very amenable.

Summary of Results.

The lecturer projected on the screen a table comparing the mortality of liver abscess treatment by open operation with that of treatment by repeated aspiration and injection. The great majority of the cases in the first group were from British army records, extending over fourteen years up to 1907, in India. Of 2,661 cases treated by open operation the deaths numbered 1,311, or 56.7 per cent. The other group consisted of 111 cases:

	Cases.	Deaths.
Rogers at Calcutta (first series) ...	19	3
Thurston in Bengal ...	48	11
Chatterji in Calcutta ...	33	2
Talbot in Mesopotamia ...	11	0

This gave a mortality of 14.4 per cent., or one-fourth of the mortality by the other method. At the London School of Tropical Medicine 12 cases had been treated without a death, but these cases were less acute than those commonly met with in India.

In conclusion, the lecturer touched upon amoebic abscess of the spleen, a rare complication of amoebic dysentery, of which, however, he had met with several cases in Calcutta, which had yielded to repeated aspiration and injection as in the case of liver abscess. If the abscess was close to the skin the punctures could be made a little to one side. Of amoebic abscess of the brain secondary to abscess of the liver a number of cases had been reported, especially from Egypt. He had not met with it in Calcutta, probably because the brain was not usually examined in *post-mortem* cases. He suggested that the fatal effects of amoebic cerebral abscess must be mainly due to pressure symptoms, and that an early decompression operation, followed by emetine injected subcutaneously morning and evening in the hope of bringing about the destruction of the causative amoebae, as well as repeated aspiration as necessary, might be tried. There would, however, almost inevitably be some loss of brain function, even if a fatal result was averted.

Memoranda :

MEDICAL, SURGICAL, OBSTETRICAL.

THE RECOGNITION OF AORTIC INCOMPETENCE.

On reading Dr. Brockbank's article on aortic incompetence I was struck with the following remark: "I also met with it from time to time in insurance work in supposed healthy persons, men and women, and in people with *known aortic stenosis but unsuspected incompetence*." Is it not an established fact that in order to make a diagnosis of aortic stenosis three essentials are necessary: (1) a thrill over the aortic area, (2) enlargement of the left ventricle, (3) definite signs of aortic regurgitation?

Surely the mere presence of a systolic bruit at the base can in no way justify a diagnosis of aortic stenosis.

In regard to Dr. Brockbank's remarks on syphilis in aortic regurgitation the following figures may be of interest:

Comparison of the Incidence of Rheumatism and Syphilis in Aortic Regurgitation and Mitral Stenosis.

	Cases.	Per cent.
<i>Aortic regurgitation, 121 cases:</i>		
Admit syphilis	24	= 19.81
Wassermann reaction strongly positive	30	= 24.71
Wassermann reaction positive	17	= 14.05
Rheumatic fever } Chorea } Rheumatism }	28	= 23.14
No history of syphilis } Wassermann negative } No history of rheumatism }	22	= 18.18
<i>Mitral stenosis, 57 cases:</i>		
Admit syphilis	9	= 9.28
Wassermann strongly positive	9	= 9.28
Wassermann positive	8	= 8.25
Rheumatic fever } Chorea } Rheumatism }	59	= 60.82
No history of syphilis } Wassermann negative } No history of rheumatism }	12	= 12.37

C. H. BROCKBANK.

ANTIMONY IN SYPHILIS.

In the Medical Section of the Medical Congress at Cape Town in October, 1921, I referred to the beneficial effect of antimony treatment in some cases of syphilis I had treated at Durban: The injections had been given daily or on alternate days until all signs of active disease had disappeared, and in each case the salt was dissolved in boiling water just before the injection was given. It was not found necessary to use more than $1\frac{1}{2}$ grains of tartar emetic for an intravenous injection, and as a rule this was dissolved in 3 c.cm. of boiling saline. Similar success was obtained when antimonium sodium tartrate was used; but after the usual tolerance had been acquired 2 grains of this salt was injected on alternate days. The toxic effects of the treatment were not severe enough to interrupt the continuous series of injections.

CASE I.

A native had extensive anal condyloma, right-sided keratitis, and syphilides over the face, all of four months' duration, following a primary sore in November, 1920. Treatment with antimonium sodium tartrate intravenously was begun on August 30th. Though he received no other form of treatment, the rash and keratitis had disappeared in six days (after $4\frac{1}{2}$ grains), and the anal condyloma was dry. The injections were continued for another week, but the case could not be followed up further, as the Department for Public Health objected to my gratuitous visits to the Durban gaol even at the request of the district surgeon. At the commencement of treatment this case gave a strong positive reaction to the Wassermann test.

CASE II.

On September 23rd I commenced to treat an Indian with strong positive reaction and multiple scrofulous syphilides which were covered with a highly offensive discharge. He received $9\frac{1}{2}$ grains of the potassium salt in twelve days. The initial dose was $\frac{1}{2}$ grain, but he was soon able to tolerate $1\frac{1}{2}$ grains dissolved in 3 c.cm. of saline. On the third day the sores were dry and the offensive smell had gone. He received no other treatment during the course of injections, but commenced to take iodides and mercury by the mouth on October 4th.

CASE III.

On October 25th I commenced a series of injections of tartar emetic in an Indian who also received potassium iodide 7 grains and liquor hydrargyri perchloridi 1 drachm by the mouth thrice daily. He gave a strong positive reaction to the Wassermann test, and the skin was covered with syphilides of four months' duration. He received an initial dose of $\frac{1}{2}$ grain, which was gradually increased to $1\frac{1}{2}$ in 3 c.cm. saline. On the third day the rash was seen to be fading. At the end of three weeks, or after a total of 15 grains had been given, the rash was decidedly better, but still desquamating. Progress was not so evident during the fourth week. He received a total of $23\frac{1}{2}$ grains in thirty-two days, and was given 3 c.cm. of colloidal sulphur during the fifth week. He then absconded, as he said he was fit to return to work, but the Wassermann reaction was still strongly positive.

CASE IV.

On September 17th I began treatment of an Indian employed at the "bakery." He had extensive leucoderma syphilitica of both forearms, paronychia (associated with discharge) of fingers and toes, ulceration of the right nostril and the corner of the mouth, and a badly furred tongue. I commenced with an intravenous injection of $\frac{1}{4}$ grain and worked up to $1\frac{1}{2}$ grains of the potassium

was dissolved in 3 c.cm. of saline. He received 13½ grains in fifteen days without other treatment, then potassium iodide 7 grains and liquor hydrargyri perchloridi 1 drachm three times daily for a fortnight, and then no treatment for six weeks. On November 29th he was clinically free from syphilis and the blood gave a negative reaction to the Wassermann test, which was strongly positive when the treatment began. In this case the tongue was the last to clear, the ulcers were all dry after the fourth injection, and the leucoderma cleared up very rapidly.

Where tartar emetic is used in freshly dissolved solution and the patient kept under the influence of the drug for a continuous period of three weeks to a month, I do not think that the results obtained are any inferior to those due to arsenic.

F. G. CAWSTON, M.D. Cantab.

ETHYL IODIDE TREATMENT OF RINGWORM.

The treatment of ringworm of the scalp in school children by the "ethyl iodide" method was described in the BRITISH MEDICAL JOURNAL by Dr. W. P. Elford (June 26th, 1920, p. 657), and as some treatment of this complaint other than x-rays was required in Bradford I introduced the method into one of the school clinics, and modified it somewhat in accordance with my own experience. We have here an x-ray installation for treating these cases, and the need for another efficient means of treatment arose from the fact that the specialist and staff of the x-ray department, in spite of all their efforts, were getting more cases than they could keep up with, so that children often waited from one to three months before their turns for x-rays arrived. Despite palliative treatments these children sometimes became considerably worse, and formed a serious focus of infection before they were cured.

The course adopted here was to refer all the worst cases—those with several patches of ringworm—for x-ray treatment. Those with one, two, or sometimes three, patches were treated at the clinic. The hair is cropped closely, or shaved, over the affected areas and for at least half an inch around the areas, and then tincture of iodine (B.P.) is rubbed in with cotton-wool swabs or thick soft camel-hair brushes. The affected areas are then sprayed with ethyl chloride (as used for local anaesthesia), the head covered with a clean cotton cap, and the parent instructed to shampoo the child's head at night. But not to use any greasy or other medicament to supplement the treatment. I have found it necessary for the child to attend six mornings a week for at least two weeks for repetitions of this treatment, and thereafter according to the apparent progress of each individual case. It has been difficult to secure this regular attendance, as parents are frequently very indifferent to this complaint and to the resultant loss of school time. A recent calculation showed that in three months, of all the cases seen at this clinic, 4.25 per cent. were attending for scalp ringworm, and their treatment amounted to about three times as much per cent. of the total treatments given.

Records were kept of 50 cases treated by me in this way, and the results were as follows:

Twenty-seven cases were cured in three weeks or less, without signs of subsequent relapse in one month. Twelve cases were allowed by the parents to attend irregularly, and ultimately to lapse; some of these are yet uncured. Six children attended irregularly, and took nearly five weeks to cure in some instances. Four children attending extremely irregularly are still uncured after two to four months from the first treatment. The other case of the 50 was a child who attended regularly, and appeared cured, but twice relapsed within a month, and is now attending again. Her parents refuse x-ray treatment. I believe she is a case of reinfection from some constant source near home. Subsequent observation of all cases has been a routine, and in many cases these results were checked by microscopic examination.

These figures are very few to base opinions upon, but it may be noticed that of the 28 who attended quite regularly for three weeks (or sometimes only two weeks) only one relapsed, all the others being yet quite free from the complaint. So far, when x-rays are not available or are refused, I have found the above method the most useful and reliable in treating children. The drawbacks are the length of time involved, and the necessity for regular daily attendance on the part of the patient. It is therefore still to be hoped that an efficient and quicker method of treatment will soon be established.

M. W. GIFFEN, M.R.C.S., L.R.C.P.,
Assistant School Medical Officer.

Bradford.

Reports of Societies.

ENDOTHELIOMA OF THE LARYNX.

A MEETING of the Section of Laryngology of the Royal Society of Medicine was held on February 3rd, with Sir WILLIAM MILLIGAN, president of the Section, in the chair. Mr. WALTER HOWARTH showed a patient, a married woman, aged 40, who had been operated upon for the rare condition of endothelioma of the larynx. She was seen in May, 1921, and had a history of hoarseness for two years previously. Laryngological examination showed a smooth red swelling occupying the anterior two-thirds of the left ventricular band, and completely hiding the left vocal cord. It was thought that the condition might be a lipoma. When examined by the direct method it was found to be more extensive than was at first thought, and the cord was found to be fixed. Laryngo-fissure was performed in June, 1921, and the tumour, including the whole of the left ventricular band and vocal cord and one-third of the ventricular band and vocal cord on the right side, was removed. Bleeding was very violent and rendered the operation most difficult, but the patient made an uninterrupted recovery. Sections of the tumour had been prepared and examined by Professor S. G. Shattoek, who pronounced the tumour to be endothelioma of the larynx. Slides and a drawing of two typical portions were shown. Sir WILLIAM MILLIGAN suggested that the condition was a unique one, and Dr. INWIS MOORE said that there was no record of a case of endothelioma of the larynx in the literature. Mr. F. H. DICKER, however, stated that a condition described as a mixed tumour, partly endothelioma, was recorded in the 1920 volume of the Mayo Clinic records.

Mr. HOWARTH also showed a case of sarcoma of the ethmoid and antrum in a child, aged 9, with three months' history of swelling of the nose and difficulty in breathing at night. There was a diffuse, firm swelling on the left side of the nose, and intranasally a large ragged polypoid growth which bled easily. There were stony hard lumps at the angles of the jaw and on the right side of the neck. Mr. HOWARTH said that he proposed to treat the case by employing radium both inside and out. Mr. HERBERT TILLY said that he thought the growth arose from the left ethmoidal region and eroded through the septum to appear at the right side. He suggested deep penetration x-rays as the best method of treatment in such a case, and mentioned a similar case which he had seen cured by this method. Mr. MCGRAVE WOODMAN and Dr. WILLIAM HILL, however, preferred the use of radium. Sir WILLIAM MILLIGAN mentioned that in one of three such cases which had come under his notice Coley's fluid had apparently caused the growth to disappear. He suggested that in inoperable cases a combination of the different methods in use should be employed.

Ulceration of Malignant Oesophagus into the Tracheal Bifurcation.

Mr. H. V. FORSTER exhibited a specimen showing ulceration of a malignant growth of the oesophagus into the tracheal bifurcation, resulting fatally. The patient was a man, aged 45, who, when taking tea, was seized with a violent fit of coughing. The doctor called in found pyrexia, with physical signs suggestive of pneumonia. Some improvement took place, which permitted him to come for examination in September, 1921. He was much wasted and could not take nourishment. Although his sister said he had complained of vague pains in the chest for several months, yet the patient himself only related the history of a week's illness. Laryngeal examination did not give any positive information. Water, when taken, was almost immediately coughed up. X-ray examination by Mr. R. E. Roberts revealed complete arrest of food at the ninth dorsal vertebra, and a photograph demonstrated the trachea lined by coughed-up bismuth food. The oesophageal appearances were typical of malignant structure. The patient was admitted to Liverpool Royal Infirmary and died within a few days of exhaustion and septic pneumonia. The post-mortem specimen (which was exhibited) showed perforation just below the bifurcation of the trachea by malignant disease originating in the oesophagus. Dr. WILLIAM HILL said that such perforations were more usual into the left bronchus; Sir WILLIAM MILLIGAN, however, mentioned two other cases of perforation into the trachea.

Suction Apparatus for Nose and Throat Operations.

Mr. C. K. MOSLEY demonstrated a suction apparatus for nose and throat operations, which was intended to keep the operating area free from all blood and discharges, and which, in his opinion, did away with any need for swabs. He said that it had proved particularly useful in bronchoscopy and in operations on the nasal passages. Dr. F. E. SHIPWAY said that he used a similar suction apparatus made by the American Sorensen Company, and testified to the great comfort to both operator and anaesthetist that such a suction apparatus could give.

Other interesting cases were shown by Sir JAMES DUNDAS-GRANT, Mr. T. B. LAYTON, Mr. LESLIE POWELL, and Dr. DAN MCKENZIE.

ANAPHYLAXIS AND ANAPHYLATOXINS.

At a meeting of the Section of Pathology of the Royal Society of Medicine, held at the National Institute for Medical Research, Mount Vernon, on February 7th, Dr. H. H. DALE, who presided, gave an account of some work which he and Dr. C. H. KELLAWAY had been doing on anaphylaxis and anaphylatoxins. He said that there were two main conceptions, with many variants, of the process which occurred in the so-called anaphylactic shock. The first, which he might call the cellular theory, attributed the anaphylactic condition, particularly in the guinea-pig, to a fixation or predominant location of the antibody in the actual living cells of the animal; the second supposed the production of a toxin, as the result of the formation of an antigen-antibody complex in the body fluids. The basis of the anaphylatoxin theory was the discovery that normal guinea-pig serum, treated with various substances, including certain colloids, had an abnormal toxicity conferred upon it, so that when injected intravenously into a normal guinea-pig it produced symptoms—or even death—similar to what was seen when an animal had anaphylactic shock. But the symptoms, although similar, were, according to the investigations of himself and his colleague, not identical.

Their first experiments gave what he regarded as direct evidence in favour of the conception that the cause of the anaphylactic shock in the guinea-pig was the union of antigen and antibody in the living cells, causing the intense contraction of the plain muscle. . . . in the bronchioles, and that the presence of the . . . in the blood was not sensitizing but protective. How, then, were the anaphylatoxin phenomena to be explained? Here he described a new series of "diffuse investigations" on the formation of the anaphylatoxins, in which Dr. Kellaway and he had employed mixtures of serum with agar and with starch. Their first experiments were directed to determining the earliest signs of any protein cleavage. They injected into a guinea-pig 5 c.cm. of a serum and agar mixture before incubation, and it produced no symptoms whatever, but after a two hours' incubation of the mixture, on injecting 2 c.cm. the animal nearly died, and there was a fatal result with 2.5 c.cm. Whatever else happened during the intoxication of the serum by the digestion of the agar or the starch, it was certainly nothing in the nature of protein cleavage, and this opinion was confirmed by taking the refractive index and by examination for other crude physical changes. No change in viscosity could be detected during the time the mixture was becoming toxic; the only thing that could be detected was that the incubated mixture, although perfectly clear by transmitted light, showed under the ultra-microscope an excess of larger aggregates, and these could be filtered by a sufficiently fine filter and the toxicity reduced. On the other hand, the suggestion made in some quarters that the starch mixture was not really anaphylatoxic at all, and that if it were only centrifuged hard enough the toxicity could be got rid of, was proved not to be the case. Filtration through paper, which it had been claimed would destroy toxicity, did not do so, though the Berkefeld filter would under certain conditions cause a reduction in toxicity.

Dr. Dale went on to compare the symptoms produced by these anaphylatoxic preparations with those seen in acute anaphylactic shock. In all cases with the anaphylatoxins there was a greater element of collapse; the suffocating closure of the bronchioles, which formed the centre of the picture in true anaphylactic death, although something of the kind was seen, was not so conspicuous. In most cases when the anaphylatoxins were used the first symptom was collapse of the animal, as distinguished from the first

symptom—coughing and rigidity during attempted inspiration—which was seen in anaphylactic shock. There were also certain *post-mortem* differences: with the anaphylatoxins there was more evidence of injury to the capillary endothelium than in the case of anaphylactic shock, and there was evidence that the anaphylatoxins did not produce such a predominant effect on the plain muscle as the antigen did in the specific anaphylactic reaction.

All these experiments reinforced the previous impression, that the action which the anaphylatoxins produced, although superficially somewhat of the same type, was not really the same as that which occurred in anaphylaxis; there was certainly a blocking of the bronchioles, perhaps caused partly by the contraction of the muscles, but there was something else, probably swelling of the membrane. On the theory that the anaphylatoxin represented a directly toxic agent in anaphylactic shock, there ought to be a powerful direct stimulant action on plain muscle; as a fact there was little or no excessive action on plain muscle. The anaphylatoxins did not produce their characteristic action in the absence of the blood, whereas antigen did. On the anaphylatoxic theory the case ought to be the converse—the antigen should act only when the blood was there, and the effect of the anaphylatoxin should be direct. Facts were awkward things, and they were the very opposite to expectation in this case. The anaphylatoxins would act and produce their effects when the blood was there, but they would not act on the plain muscle when isolated from the blood and suspended in an artificial saline solution. The antigen produced all its effects on the plain muscle removed from the body and suspended in saline. With regard to desensitization, one dose of anaphylatoxin desensitized to another. An anaphylactic animal could be so treated, and, being tolerant of anaphylatoxin, should now resist antigen, but it did not. It seemed evident to him that the anaphylatoxins were not direct toxins; their action resembled that produced by sudden exposure of the blood to a large extent of mildly injurious foreign surface. In some way, during the incubation of the serum, the non-nitrogenous colloid, presumably by absorption on the aggregates of protein in the serum, acquired a very great extent of surface. The probable effect of incubating the serum-starch and serum-agar mixtures was to produce the optimum dispersion of the foreign colloid so as to present the maximal extent of such surface to the blood.

In the course of a conversational discussion Dr. Dale said that he would not like to make any statement as to the mechanism of the reaction in man.

Culture Medium for B. diphtheriae.

At the same meeting Captain S. R. DOUGLAS brought forward a new culture medium for *B. diphtheriae*: Loeffler's media had two disadvantages: first, their great opacity, so that when the colonies had fully developed the individual colony was not easily seen; and, secondly, the amount of serum required. In most of the substitutes it was a question of adding alkali, but this changed the albumin, so that it became a very unsuitable food for the organism. He had worked on serums to which a certain amount of trypsin had been added, the treated serum being then added to agar, and this medium grew colossal colonies, but at the same time it grew many other organisms extremely well, so that it was difficult to see the colonies of diphtheria. Ultimately he found the best results obtained by the use of a 1 per cent. solution of potassium tellurite, added to melted agar, and used with trypsinized serum. With a medium so treated, he had got the diphtheria colonies with an almost black centre, while the contaminating organisms were almost colourless. He gave full details of the preparation of the medium.

ADDISON'S DISEASE TREATED BY SUPRARENAL GRAFTING.

At the meeting of the Clinical Section of the Royal Society of Medicine on February 10th Dr. A. F. HURST brought forward a case of Addison's disease with severe anaemia which had been treated successfully by suprarenal grafting.

The patient, a man aged 41, was admitted under his care in November, 1920, with great muscular weakness and pigmentation of the skin. There was a family history of consumption, but the patient had had no previous illnesses. For a year past he had suffered from increasing weakness; he was soon exhausted after walking, and recently he had begun to vomit after meals. He also suffered from frequent

headaches, and it was noticed that his skin was gradually becoming darker. In certain areas, such as around the nipples and genitals, it was almost black, and elsewhere there were dark brown patches and minute black spots. There was some pigmentation in the mouth, especially on the lower alveolar margin, where his denture had pressed. All his teeth had been removed some months before on account of severe sepsis. The general muscular development was good; there were no signs of active or healed tuberculo-sis in the chest, and the Wassermann reaction was negative. Gastric analysis by the fractional method showed complete achylia, which was confirmed later. The spleen was slightly enlarged and appeared to be abnormally hard; the liver was also slightly enlarged and hard. The systolic blood pressure on admission was 120 mm. Hg, and at the end of four months it had fallen to 75 mm. Hg. The percentage of haemoglobin was 60. The red cells numbered 5,120,000 per cubic millimetre, and the white cells 4,101. Treatment with hydrochloric acid by the mouth, suprarenal extract in large doses, and injections of 1 in 1,000 adrenalin hydrochloride caused no obvious improvement.

In March, 1921, a suprarenal gland removed from a man who had just died as the result of an accident was grafted into the subcutaneous tissue of the inguinal region. The blood pressure remained as before. Some experiments a good many years ago in America showed that in animals better results had attended the transplantation of a suprarenal gland to an organ than merely grafting under the skin, and therefore it was determined to try the effect of grafting into an organ in this case. The easiest organ for this purpose was the testicle. After looking for some time for a suitable opportunity, the suprarenal from a foetus removed just before death was grafted by Mr. Tanner into the capsule of the left testicle of the patient. At first there was no obvious improvement, but gradually after an interval of two or three months the patient began to improve, and it could now be said that he was infinitely better than when the operation was performed. A month after the second operation the haemoglobin percentage was 43, the red cell count 2,070,000, colour index 1.0, and the leucocytes 7,400. The haemoglobin continued to fall, and a blood transfusion was performed, and the patient was again given hydrochloric acid and iron by the mouth. He then began slowly to improve, and presently was discharged from the hospital and returned to his home to attend to his private affairs. He was now feeling very much better; he had not vomited at all, but the pigmentation appeared to be unaltered. The systolic blood pressure had risen to 115 mm. Hg, and the haemoglobin percentage was 80. The spleen was still palpable. The suprarenal graft could be made out as a nodule on carefully palpating the testicle.

Sir WILLIAM HALE-WHITE, who was in the chair, said that this was the first time that this subject had been brought before the profession in London, and he thought that Dr. Hurst and his colleagues in this case (Mr. W. E. Tanner and Mr. A. A. Osman) were to be congratulated. It seemed beyond doubt that the man had Addison's disease, and that there had been improvement since this operation was done.

Mr. W. E. TANNER referred to the importance of having young suprarenals for the purpose of grafting before there was any great increase in the amount of connective tissue in the organs. In the full-time foetus the suprarenal was not a definite capsule at all; it was merely a mass of tissue among other masses, and it was almost impossible to dissect it out without doing a great amount of damage. He raised the question of possible advantage in putting these grafts where there was quite a considerable amount of sympathetic ganglia. If it was practicable to put them in the region of the pre nortie sympathetic ganglia such a course might prove very successful.

Advantages of Cholecystectomy over Cholecystotomy.

Mr. R. P. ROWLANDS brought forward a case to illustrate the advantages of cholecystectomy over cholecystotomy. It was a case in which, on operation, he found a ruptured gall bladder, which he removed with difficulty, and when it was out discovered that there was a stone in the cystic duct, which would have been overlooked had the gall bladder not been removed, and would have rendered the operation unsuccessful. It appeared that the patient had been the subject of a previous operation, when gall stones were removed; his recovery had been very tardy, and soon after getting back to work he fell ill again with a violent pain in the right hypochondrium. Indeed, his condition after the first operation was so bad that he was unwilling to face a second without an assurance that it would not condemn him again to continuing invalidism. It seemed to the speaker that whenever possible, when the disease was limited to the

gall bladder, and if the common bile duct was clear, the gall bladder should be removed. It was not always possible to do this as a primary operation because the gall bladder was so convoluted and involved that often it was physically very difficult to separate, and therefore primary cholecystotomy might be right and proper. But the disease which caused gall stones was really in the wall of the gall bladder, and therefore it seemed logical to remove the cause. Another reason was the real risk of cancer; he had removed five gall bladders for lesions which he thought were merely inflammatory, and yet under the microscope they exhibited primary carcinoma.

Sir W. HALE-WHITE said that his experience was that the draining of the gall bladder had generally been a very good operation, and most cases remained perfectly well afterwards for a long time of years. Only twice in his life had he seen an unsuccessfully drained gall bladder. He thought that his experience was to the point because patients upon whom an operation had been unsuccessful very commonly went to a physician.

Mr. ROWLANDS said that his own experience was contrary to that of Sir W. Hale-White, but he repeated that there were manifest precautions to be observed before the gall bladder was removed, and in particular no one ought to remove the gall bladder unless he knew that the common bile duct was clear.

INFLAMMATORY STRICTURE OF THE RECTUM.

At the Medical Society of London, on February 13th, an address on inflammatory stricture of the rectum was delivered by Professor HENRI HARTMANN, Hon. F.R.C.S. Eng., of Paris, who was formally admitted to the honorary fellowship of the Society on the same occasion. Mr. JAMES BERRY presided over a very large and distinguished audience.

PROFESSOR HARTMANN'S ADDRESS.

Professor HARTMANN, after expressing his pleasure at speaking in the home of the oldest medical society in the kingdom, said that he intended to limit his address to the strictures which he had himself observed, as one surgeon's experience was more useful than many scattered observations gathered from literature. Inflammatory stricture of the rectum was somewhat rare; he had observed only 85 cases. It was supposed that women were disproportionately affected, but many of the published statistics which supported this view had been gathered largely from institutions for women suffering from venereal disease. His own statistics were collected from a clinic of general surgery, and these showed that out of 85 cases only 50 were those of women. As for age incidence, the greater number of the patients (53) were between 30 and 50; only one was over 60 and only two under 20. There was undoubtedly syphilis in 30. In 10 patients—putting aside the cases of purely tuberculous stricture—pulmonary tuberculosis existed before the first symptoms of stricture. Chronic inflammation of the uterus appeared only exceptionally to play a part. Dysentery was to be detected in only one case. One of his patients was suffering from leprosy, and it seemed possible that leprosy, like syphilis and tuberculosis, was a starting-point of stricture. He did not think that chronic constipation had any influence on the etiology.

In inflammatory strictures the lesion occupied a fairly large space in the rectum. Generally it was in the lower region, from 2 to 6 cm. above the anus. In three cases the stricture extended along the entire rectum; usually it was cylindrical in shape. The stricture itself was composed of sclerous tissue, but, as he showed by photomicrographs, there were in many cases evidences of neighbouring syphilitic or tuberculous lesions. The first symptoms, before the stricture developed, were nearly always a feeling of rectal fullness, with frequent desire to evacuate and painful discharge; the faeces were tape-like, and the patients suffered from more or less permanent distension. He had never seen any case of complete obstruction, though a few examples had been published. In 28 of his 85 cases he had observed fistulae, often numerous, communicating with one another, and presenting the peculiarity of nearly always opening into the rectum, just below the stricture.

Treatment by dilatation was useful, but must be carried out gently. A bougie must be selected which passed through the stricture without force and without pain. He used women bougies covered with gum; two or three of these were introduced each time, and the procedure was repeated every other

day, commencing with the bougie which had been last used on the previous occasion, and then introducing one or two of larger size. Each bougie should be left in position a few seconds only. When a sufficient size had been reached, the treatment should be continued once a week. This treatment never cured the disease, and in some cases when the symptoms of proctitis were predominant, it would aggravate them. By a complete extirpation of the diseased region he had obtained permanent cures when the lesions were limited to the termination of the rectum. These cases were rare, for the wall was often inflamed above the stricture, and at the beginning of the trouble, when the lesion was limited, the patients who were scarcely suffering at all would refuse operation. He preferred the intra-sphincter amputation, very much like Woodhead's operation for haemorrhoids. The dissection of the region surrounding the anal canal was rather difficult, and must be performed with a bistoury behind the sphincter. It was generally possible to isolate the rectum with the finger, to strip it up, to lower its superior end, and to stitch it to the skin. The dissection must be carried very high, and the perineal pre-rectal cul-de-sac opened when this was necessary. First of all he put some small drainage tubes beneath the sutures, and in his latest operations he had a counter-opening in the posterior part of the ischio-rectal fossa. He had operated by excision of the rectum in 34 cases, with good results in 32; two patients died of pelvic cellulitis, these two deaths occurring in the earlier part of his practice. Twice he had performed an abdominal-peritoneal excision on account of stricture reaching the inferior half of the pelvic colon, with one recovery and one death. It was necessary to incise and curette the fistulae when these existed. In some cases he had been obliged to combine the excision of the rectum and the curetting and incision of the fistulae. Generally he had simply prolonged the incision of the rectal wall just above the stricture to perform an external proctotomy with plugging, but when it was possible he had brought down the superior angle of the rectal incision to stitch it to the skin, thus doing an autoplasmic proctotomy. When the case was beyond the reach of local treatment, and extensive suppuration had developed around the rectum, iliac colostomy was indicated. The patients almost immediately gained in health and strength. He had performed 17 colostomies, with 16 recoveries and one death from bronchopneumonia. He never did internal proctotomy, as he believed it to be dangerous on account of haemorrhage and sepsis. Altogether, only a few radical cures could be obtained in stricture of the rectum, but by combining different methods of treatment and by performing oftener perineal excision of the rectum and colostomy, life might be prolonged and the patients greatly relieved.

Mr. J. P. LOCKHART-MUMFERY said that he had practised internal proctotomy for the last fifteen years, and found it a very satisfactory operation. He must have done forty or fifty cases, and had had no disaster of any kind. He was always very careful with regard to a sepsis. The operation was not a cure, because there was a large proportion of recurrences; but there would not be recurrences if the patients were careful to keep the rectum dilated sufficiently long, and those who did take this trouble were cured permanently. He had dealt by this method with very big strictures, up to 1½ in. in length. He raised the question of whether many of these cases of stricture were not due to difficult or mismanaged labour. At St. Mark's many histories of stricture seemed to date from such labour. He believed syphilitic strictures to be very rare; the vast majority were streptococcal infections of the rectum.

Dr. HERBERT SPENCER did not think that difficult labour could be the starting point of stricture. He had seen very few of these strictures of the rectum during twenty-five years as a gynaecologist, not as many, indeed, as he saw during six months as surgical dresser.

Mr. ERNEST MILES said that chronic infective ulceration of the rectum was at one time prevalent in this country, but since the adoption of strong antiseptics it had, comparatively speaking, disappeared. At St. Mark's very few such cases were now seen. It certainly seemed as though strong antiseptics had been the means of eradicating it.

Sir CHARLES GORDON-WATSON had not seen many cases associated with syphilis. The tuberculous cases must be set apart and considered as a different class. Stricture associated with chronic proctitis could be cured for the time being by gradual dilatation, followed by periodic dilatation and by irrigation, and after the acute stage was over these cases healed very rapidly, as a rule, with the treatment of the

ulcers by zinc ionization. Severe infective ano-rectal ulceration of post-operative cause was seen occasionally. Quite recently in St. Mark's there was a case where the entire lumen of the rectum had disappeared. Very shallow strictures occurring at the ano-rectal junction and not associated with ulceration, but frequently with fistulae, were usually dealt with by treating the fistulae and dilating the stricture at the same time on ordinary rational lines. Many of these cases had a history of gonorrhoea.

Mr. GORDON TAYLOR mentioned a case of a girl, now under his care at Middlesex Hospital, with a stricture of the rectum 3½ inches long and numerous fistulae. A streptothrix had been isolated, not once but several times, and he believed the case might be definitely labelled actinomycotic stricture of the rectum. Mr. NORBURY asked whether multiple strictures of the rectum were at all common. One patient at St. Mark's had two well marked strictures with an interval of about one inch of more or less normal canal between them.

Sir ARBUTHNOT LANE said that most of the strictures he had seen had been produced by the surgeon. A few had been produced by gonorrhoea, almost all in the female, and a number, which had caused him a certain amount of trouble, had been due to ulcerative colitis. It was a great disappointment to have removed the large bowel, apparently successfully, the patient getting strong and well, and then within three years to have him turning up again with ulcer in the rectum. Mr. A. J. WALTON referred to the relationship of stricture of the rectum to ulcerative colitis. He had come across a number of cases of ulcerative colitis in which the condition had spread down to the rectum.

Professor HARTMANN, who replied in French, could not accept the theory that the stricture often followed difficult labour. The great majority of his women patients had never had children. He himself had not seen a stricture formed in that way. He thought that multiple strictures were extremely rare; he had seen only one case. He considered extirpation the ideal treatment, although he thought the cases which could be treated ideally were only the early cases, and consequently the rectal surgeon did not very often see them.

Sir ANTHONY BOWLEY proposed a vote of thanks to the distinguished visitor, who, he said, was known throughout the world as the author of very valuable papers, chiefly on abdominal subjects, and especially on the genito-urinary tracts. It was a matter of regret to have a French surgeon in their midst. *Entente* find readier expression than in the medical profession, for the profession, both in France and England, had the same ideals, and in war and peace worked for the same end. In speaking of Pasteur and Lister he mentioned that the former worked at Strasbourg in Alsace, and he congratulated their colleague upon the fact that Strasbourg was again in French possession, and that there was a French professor in Pasteur's chair.

The vote of thanks, which was seconded by Mr. W. E. MILES, was carried by acclamation.

An exhibition of specimens of rectal stricture had been arranged by the society, and Mr. JAMES BERRY expressed the society's indebtedness to the various museums which had contributed. The exhibition illustrated the great variety in the nature of the stricture, and included some examples of perforation, both by spontaneous ulceration and by the injudicious use of the bougie.

SCARLET FEVER AND SCARLATINIFORM RASHES.

AN ordinary meeting of the Manchester Medical Society was held on February 1st, with Sir WILLIAM MILLIGAN, the new president, in the chair, when Dr. R. W. MARSDEN opened a discussion on scarlet fever and scarlatiniform rashes. He spoke of the advisability of more careful selection of patients for removal to hospital when suffering from scarlet fever, and the necessity for having good evidence that the patient is suffering from the disease before sending to hospital, and not removing on suspicion. He emphasized the advisability of nursing and isolating at home all cases which can be so dealt with. He then pointed out the impossibility in many cases of making a differential diagnosis between scarlet fever and a scarlatiniform eruption from some other form of toxæmia by inspection of the rash alone, and urged the necessity of not only fully inspecting the rash in all parts of the body, but of taking all the other points into consideration before coming to a conclusion. He thought it better not to send mild cases of scarlet fever to hospital, and wondered if many cases so sent were really not scarlet fever at all.

Dr. ST. CLAIR McCLURE, who followed, spoke of the relative infectivity of severe and mild cases of scarlet fever and other diseases, and came to the conclusion that the infectivity of mild cases of scarlet fever was very high. The point was an important one, and he depended upon its acceptance to explain, in some part, the prolongation of the wave of scarlet fever prevalence in 1921. He discussed the change of type of the disease during recent years, rendering the problem of diagnosis in many cases very difficult at the present time, although he believed that the great mass of cases notified were truly scarlet fever yet there were a number in which differential diagnosis between mild scarlet fever and mild influenza was not clear. No doubt with two epidemics prevalent at the same time there would inevitably occur many cases of mixed infection. As regards removal of patients to hospital, he thought medical officers of health would agree that if isolation accommodation was practicable in the home and the parents were dependable, it was preferable to keep at home. But figures in Manchester showed that there was a very definite advantage to individual households in the removal of cases to hospital. The greater the promptness in removing the patient the less would infection spread amongst family contacts. This was shown by an investigation carried out over a series of years.

Dr. F. E. TYLCORE dealt with certain points of importance in the differential diagnosis between scarlet fever and other conditions which cause scarlatiniform rashes. In the first place, the throat in scarlet fever showed a general injection; if there was no injection it was not scarlet fever, if there was an injection it might be scarlet fever, or it might be something else—some other points would have to decide. The larynx was unaffected in the early stages of scarlet fever; to that there was no exception. Cutaneous irritation—though he was interested to hear of the recent experience to the contrary—as a rule, he looked upon as against a diagnosis of scarlatina, though he admitted exceptions. When the rash had all but passed away two features were important to look for: (1) Pinpoint papules remaining on the extensor surface of arms or legs, and (2) the red punctate raising of the deep hair follicles on the calf. He emphasized also the differences in the skin of the patient who had just lost the rash of (1) scarlet fever, (2) measles, and (3) rotheln. In scarlet fever the skin was pale, sallow, and parchment-like; in measles, dirty-looking and pigmented; in rotheln perhaps there were traces of a fine braunish desquamation. Scarlet fever peeling never occurred at a given spot until the rash had faded from that spot; in food and drug rashes, on the other hand, scaling and an erythema were often present on the same part of the body at the same time. He thought the time of the year in which any given fever had its maximum prevalence was a point often lost sight of when making a diagnosis between one exanthem and another. He had found prevalence and mortality curves well worth bearing in mind. He had not found joint troubles quite as early as Dr. Marsden had said, speaking generally. He was very glad to hear him plump for the typical tongue as being a pathognomonic point at a given date. He was pleased to hear attention drawn to the coincidence of other fevers, and instanced a child who had five fevers overlapping one another. He found the persisting nasal discharge of a thin or possibly sanious character to be a much more fertile source of return cases than was persistent otorrhoea. Prodromal rashes of variola, varicella, and of measles were often scarlatiniform, but were very transient.

DIET IN NEPHRITIS.

A MEETING of the Liverpool Medical Institution was held on February 2nd, with Dr. HILL ABRAHAM in the chair, when Dr. C. O. STALLYBRASS described a case of exanthem subitum, drawing attention to the clinical picture and epidemiology.

Dr. H. S. PEMBERTON read a short paper on diet in nephritis. In introducing the subject Dr. Pemberton contended that the maintenance of adequate nutrition should always be recognized as one principle in the management of chronic renal disease. The question of diet might be considered from two sides—a receptive and an eliminating. There were certain changes in the receptive side (gastro-intestinal mucosa and portal system) often associated with chronic nephritis, and unless these were recognized the diet might prove inadequate from non-renal causes. Changes on the eliminating side were often directly associated with renal disease, the degree of which might be determined by clinical or biochemical means. The fate of known diets may in part be investigated by means of the

renal test meal combined with estimations of blood-urea and total nitrogen content of the urine. Many renal cases, irrespective of type, were still deprived of proteins. Those which needed proteins appeared to be: (1) Cases of albuminuria without retention of nitrogen; (2) cases with or without albuminuria which retained nitrogen, but did not show an elevation of the normal blood-urea content; and (3) certain anomalous cases where the amount of protein which could be tolerated was only determinable by trial. Proteins would seem inadvisable in cases which showed high blood-urea concentrations, and hence one of the most generally useful controls on dietetic management was periodic estimation of the blood-urea content.

The Peptic Ulcer.

Mr. K. W. MONSARRAT read a paper entitled "The peptic ulcer," and reviewed records of the cases on which he had operated during 1921. These were 48 in number, 41 being men and 7 women. In 34 instances the ulceration was gastric, in 8 duodenal, and in 6 jejunal. Twenty-five of these cases had been treated by partial gastrectomy, and to the indications for this operation Mr. Monsarrat particularly directed his attention. There had been no mortality among the cases under his care, and he considered that the operation was well borne. Certain cases were suitable for sleeve resection, but for the greater number of inveterate ulcers the Polya operation was the best procedure. He preferred the posterior Polya operation, and had not met with the stenosis which had led other surgeons to prefer the anterior operation. He discussed the relations between functional disturbances of the pyloric mechanism and the incidence of ulcers. He considered that the basal condition of the etiology of ulcer was the disturbance in the normal correlation between gastric and pancreatic secretion. He exhibited detailed records of the cases to which he had referred.

Reviews.

ESSAYS ON SURGICAL SUBJECTS.

SIR BERKELEY MOYNIHAN has republished in a small volume a number of essays¹ which had previously appeared chiefly in the *British Medical Journal* and *British Journal of Surgery*. The book opens and the book ends with the texts of two addresses: the first is the Murphy Memorial Oration given before the American College of Surgeons at Montreal; the second is entitled "The most gentle profession," and was delivered to nurses at Leeds. We have selected these two addresses for mention at once because they present Sir Berkeley Moynihan in his best vein. Well though he writes—and he has sometimes written extremely well—it is as a speaker, as an orator in fact, that he finds his real *milieu*. Not all great orators can be reduced to the printed page and yet remain more than shadows of their true selves. We have at one end of the scale, perhaps, Burke, at the other the present Prime Minister. Sir Berkeley Moynihan occupies a middle position. There are passages of great intensity, of an uncommon enthusiasm, which transmit themselves to the reader of his Murphy Oration. The figure of J. B. Murphy emerges passionately alive, with all his peculiarities and spiritual angularities, the greatest clinical teacher of his time. But there are long and comparatively arid parts of the speech where the voice and personality of the speaker are needed to kindle the spark. Yet as a paper, as distinct from an oration, the parts complained of contain a valuable synopsis of the history of surgery. The second address, that to nurses, is characteristic, and contains a passage on the nurse's office reminiscent of Stevenson's: "To be honest, to be kind . . ." The second essay, "The ritual of a surgical operation," may be regarded as Moynihan's *credo*, and, whether surgeons agree on detail or not, undoubtedly represents the highest technical ideal so far set before the profession.

It will be sufficient to enumerate the titles of the remaining essays, all more or less well known, though for the first time collected under one cover: Chronic gastric ulcer; dissections after gastro-enterostomy; intestinal stasis; gifts of points to medicine; acute emergencies of abdominal disease; and the surgery of the chest in relation to retained projectiles.

¹ *Essays on Surgical Subjects*. By Sir Berkeley Moynihan, K.C.M.G., C.B. Philadelphia and London: W. B. Saunders Co. 1921. (Met. Soc. No. 253; 17 figures. 2s. net.)

MEDICAL EXAMINATION FOR LIFE INSURANCE.

*Medical Examination for Life Insurance*² is a short handbook for medical men who occasionally make medical examinations for this purpose. Such a book has long been required in England. Dr. T. D. LISTER has admirably filled the gap with his most practical and useful work.

As he has an extensive acquaintance with diseases of the thorax, especially pulmonary tuberculosis, let us first of all see how he deals with the subject of "personal history of respiratory disorders" in Chapter XI. He gives valuable hints as to the significance in various cases from the insurance point of view of a past history of chronic cough, thoracic pain, blood spitting (including cases in which the blood is said to have "come from the throat"), pleurisy with or without effusion, asthma, bronchitis, pneumonia, and empyema. He records two remarkable cases of pulmonary tuberculosis which, he says, illustrate the truth of Dr. Samuel Gee's aphorism that one should never make a prognosis in pulmonary phthisis, for, if one does, there is only one thing certain—that one will be wrong. The first case was that of an athletic man, aged 32, with tubercle bacilli in his sputum and a cavity as large as an orange in the right lung, who fourteen years previously had been living with a friend who was probably consumptive. He was physically very well developed, and, in spite of his pulmonary cavity, served with distinction as an officer during the great war. After the war he was much in the same condition as before, and Dr. Lister remarks that he seems to be a "tubercle carrier." The second case was that of a medical man, aged about 30, with pulmonary cavities in three lobes, albuminuria, a pulse of 130, a pale face, and a blanched palate. Dr. Lister stated that in his opinion such a risk would probably die at the rate of 70 per cent. in the year. The insurance company thereupon granted the applicant an annuity for a purchase price of £700, allowing £230 a year to the annuitant. Dr. Lister adds that the annuitant in question is still living—a "fibroid wreck"—in a good climate, and that the insurance office has already lost over £2,000 on the transaction. As illustrating the occasional development of excessive weight and gouty habit after pulmonary tuberculosis, Dr. Lister instances an energetic and distinguished business man, who was attacked with "consumption" about sixteen years ago, when he weighed 9 st. 10 lb. He was treated in sanatoriums and has since then lived an open-air life; he is now a florid, heavy man of the gouty type, weighing well over 14 st., but is still found to have physical signs of a cavity in the apex of the left lung. Another man, over 50 years of age, applied for insurance, with an ankylosed angular curvature of the spine, from old tuberculous causes. He was of the florid, gouty type, and had a high blood pressure and a trace of albumin in the urine. He died of cerebral hæmorrhage a few years later. Dr. Lister remarks that neither of these two last cases was insurable, owing to the "excessive rebound" from tuberculosis to the "gouty" type. Dr. Lister dwells on the great importance, when there is a question of past pulmonary tuberculosis, of taking into consideration, not only the evidence furnished by actual examination of the chest, but also the nature of the family history, the occupation, habits, build, height, weight, blood pressure, and signs and history of disorders such as "indigestion." He regards a low blood pressure as "an adverse feature, when there is any reason whatever to suspect a liability to tuberculosis."

The foregoing may serve to give an idea of the practical hints and useful information and interest with which the whole book is full. It should be in the hands of all general practitioners who occasionally have to furnish life insurance reports, but may with advantage and satisfaction be read by regular examiners for life assurance, and also by senior medical students.

OEDEMA AND NEPHRITIS.

The large volume by Professor MARTIN H. FISCHER, of Cincinnati, on *Oedema and Nephritis*,³ which, though now in its third edition, is not so well known as it should be to British medical men, represents the results of thoughtful original research extending over more than ten years, and is

² *Medical Examination for Life Insurance*. By T. D. Lister, C.B.E., M.D., F.R.C.S., M.R.C.P. London: Edward Arnold and Co. 1921. (Demy 8vo, pp. 168, 10s. 6d. net.)

³ *Oedema and Nephritis. A Critical, Experimental, and Clinical Study of the Physiology and Pathology of Water Absorption in the Living Organism*. By Martin H. Fischer, M.D., Eichberg Professor of Physiology in the University of Cincinnati. Third and enlarged edition. New York: John Wiley and Sons. London: Chapman and Hall. 1921. (Med. 8vo, pp. xvi + 922, 217 figures, 55s. net.)

quite different from the usual treatises which give a complete review of current knowledge with the author in the background except as the judicial authority. Professor Fischer's own views, based on experiments on the colloid chemistry of water absorption by protoplasm and the physiological and pathological corollaries, form the basis of this work. Oedema is defined as a state in which the hydration capacity of the body colloids is abnormally increased, and the causes of oedema are shown to be any substance or condition which in the circumstances existing in the body can increase the hydration capacity of any of its hydrophilic colloids; thus acids produce oedema, whereas salts, including sodium chloride, reduce existing oedema. Circulatory disturbances, as in cardiac failure, entail oxygen starvation and so the abnormal production and accumulation of carbonic, lactic and other acids; some amines and various poisons act in a similar manner. In some critical remarks on shock, added in connexion with the work done in Europe on this subject during the war, the use of colloid solutions, such as 6 per cent. acacia gum, is instanced as a practical application and acceptance of the author's colloid-chemical notions of water absorption.

The same argument given for the nature and cause of oedema is applied to nephritis: thus all the changes characterizing nephritis are, the author contends, colloid-chemical in nature and due to a common cause—the abnormal production or accumulation of acid, and of substances which in their action upon colloids behave like acid, in the cells of the kidney; to the action of these upon the colloid structures that make up the kidney are due the albuminuria, the structural changes in the kidney, the casts, and other urinary manifestations. The general rule formulated for the prophylaxis and treatment of nephritis is the avoidance and removal, as far as possible, of every condition that favours the abnormal production of acids in the kidney, or of such other substances which in their effects on the colloids behave like acid; thus alkalis, salts, and sugar should be given and the intake of water restricted; sufficient alkali should be given to keep the urine persistently neutral to litmus. A diet on vegetarian lines is better than an ordinary mixed diet, but more harm may be done by underfeeding than by overfeeding.

Professor Martin Fischer's views have met with criticism and opposition, but his book shows that he is an extremely able and energetic worker, and that his conclusions deserve serious consideration.

UROLOGY.

In the third edition of *The Practice of Urology*,⁴ by Dr. CHARLES H. CHETWOOD, no very radical changes have been made, and he has resisted the temptation, to which an author is always exposed when bringing out a later edition, of increasing its size. As he states in his preface, Dr. Chetwood's attitude towards urology is a "progressive-conservative" one. No new methods are included that have not passed beyond the experimental stage. Among the additions is a description of the author's design of universal cystoscope; it is intended to combine the advantage of a cystoscope and a cysto-urethroscope, and includes sheaths for double and single catheterization, as well as simple diagnosis. One telescope is used for all the sheaths, but a special telescope with rectangular, ocular, and direct vision is provided for operative purposes. Another instrument that is essentially the author's is a galvano-cautery to be used in partial operations on the prostate. This is used in a manner somewhat similar to the galvano-cautery employed in the now abandoned Bottini operation. As a preliminary to the employment of this instrument external urethrotomy is performed, and through the opening the instrument is passed straight into the bladder. The obstructing mass is then incised by means of a cautery knife, sliding in a groove and controlled by the finger of the right hand, the index finger of the left being inserted into the rectum so as to control the situation of the galvano-cautery. No cooling device is attached to the instrument, but a flow of sterilized solution is kept up through the urethra during the progress of the operation. It is admitted, however, by the author that the operation is of limited application, being of use chiefly in cases of contraction of the neck of the bladder. To those who have not seen perineal galvano-prostatotomy the technique makes no very strong appeal. The operation would seem to have many of the disadvantages

⁴ *The Practice of Urology*. By C. H. Chetwood, M.D., LL.D., F.A.C.S. Third edition. London: Baillière, Tindall, and Cox. 1921. (Roy. 8vo, pp. 830; 9 plates, 310 figures, 42s. net.)

of Bottini's, and to labour under the additional handicap of acquiring a preliminary external urethrotomy. However, it must be admitted that as a result of the perineal wound such complications as post-operative hæmorrhage are under better control.

A brief description is also given of perineal prostatectomy both by the intra-urethral and the extra-urethral methods. The reader is thus offered a large choice of methods of dealing with prostatic enlargement, but perhaps is not given sufficient help in arriving at a decision as to which is the method *par excellence* for any particular case.

The work includes also chapters on chaneroid and syphilis. Whether it is an advantage to deal with such subjects as syphilis, myocarditis, daercyocystitis, and tabes dorsalis in a work on urology is very doubtful. These lesions are, however, linked up with the genito-urinary surgeon's speciality, and their inclusion in a work of this kind may perhaps be justified by custom if not by logic. For the treatment of chaneroids the author still recommends the drastic methods by means of fuming nitric acid that have been abandoned in this country. He maintains that if complete destruction of the ulcers by cauterization is carried out they are transformed into granulating ulcers, which follow an uninterrupted course of repair, but for complete cure each and every sore must be reached and thoroughly destroyed, as one small untreated area may reinfest the whole granulating surface. One of the disadvantages, however, of using strong antiseptics in the treatment of chaneroid is the fact that, once an anti-septic has been employed, a search for spirochaetes as a means of differential diagnosis is rendered impossible. Sufficient emphasis has, in our opinion, not been placed on this point by the author.

The book, like most other American publications, is profusely illustrated and generally well turned out.

CEREBRAL TUMOUR.

PROFESSOR CHRISTIANSEN'S book, of which we have received a French translation, consists of a series of twelve lectures dealing at considerable length with the more strictly clinical aspects of cerebral tumours.² Three lectures are devoted to the tumours of the motor area of the brain, where the principles of localization and diagnosis are well illustrated by detailed reports of particular cases. Perhaps the most valuable of these is the third, where convulsive symptoms and Jacksonian epilepsy are considered, and where there is also a discussion on muscular atrophies of cerebral origin, a subject of great interest hardly mentioned in many textbooks. The fourth lecture deals with tumours of the occipital lobes; here a fuller reference to the knowledge gained by the experience of war wounds of this region of the brain, and, in particular, the work of Holmes, might have been expected. In the fifth lecture the differential diagnosis of lesions at the base of the brain is discussed; tumours and syphilitic lesions are considered, and remarks on ophthalmoplegic migraine and myasthenia gravis are added. The various clinical aspects of syphilitic meningitis are described in a separate lecture.

In the lecture on tumours of the pituitary body a good account of the symptomatology is illustrated by reports of cases both of acromegaly and of Fröhlich's type of dystrophia adiposo genitalis. Tumours of the cerebello-pontine angle afford material for two lectures, which are perhaps the best in the book, though we are surprised to find no mention of Cushing's notable contribution to this subject. Tumours of the cerebellum and midbrain are described in another lecture, which contains a very detailed consideration of a few cases only, and might perhaps have gained in value by a broader treatment of the whole subject. A useful and frank chapter on doubtful diagnosis follows, and the volume is concluded by a lengthy lecture on surgical treatment.

Undoubtedly the best features of the book are the careful clinical descriptions of the cases quoted and the detailed diagnostic arguments set forth. Consisting essentially, therefore, of clinical lectures it will appeal to the neurologist rather than to the student, who will perhaps find the author's method a trifle discursive. As the fruits of an extensive experience and careful and discriminating observation it may be heartily commended.

This translator, we feel sure, has done full justice to the

² Les Tumeurs du Cerveau. Par Prof. V. Christiansen, avec une préface de Prof. P. Marie. Traduction française par M. Polack. Publiée avec le concours du Dr. H. Bouctier. Paris: Masson et Cie. 1921. (Roy. 8vo, pp. 353; 105 figures. Fr. 25 net.)

original text, for the reading is easy and pleasant, so that a wider circle will doubtless be able to enjoy this original contribution to the literature of cerebral tumours.

DIETETICS.

THE fifth edition of Dr. ROBERT HUTCHISON'S work on *Food and the Principles of Dietetics*³ does not differ substantially from the fourth, reviewed in the BRITISH MEDICAL JOURNAL of February 10th, 1917. The author has revised the sections on energy requirements and rationing, incorporating results derived from war-time experience and research, and has inserted a *précis* of knowledge respecting "vitamins." He has, however, wisely resisted the temptation to change the character of the book by greatly expanding the chapters concerned with general metabolism and energetics.

Of the great merits of the book as a whole it is unnecessary to speak. One minor criticism may be passed. Dr. Hutchison cites the Report of the Advisory Committee to the Central Control Board on Alcohol, its action on the human organism, and remarks that "none of its conclusions conflicts materially with what is set out in the text of this book." Although this statement can be defended, it might have been well to add that the Advisory Committee did not endorse the favourable opinion of moderate doses of alcohol as adjuncts to digestion which Dr. Hutchison inclines to hold. The Committee concluded that the increased flow of gastric juice "is of little or no value in the process of digestion, although there is no reason to suppose that it is in any way injurious."

RADIO-THERAPY.

THE textbook entitled *X Rays and Radium in the Treatment of Diseases of the Skin*, by Dr. G. M. MacKIE, is more elaborate and comprehensive than the title would suggest, inasmuch as in addition to the actual treatment of disease its first two hundred pages contain, amongst other things, an excellent historical survey, a treatise on the physics of the subject, and a summary of instrumentation. It is stated in the preface that x rays and radium together constitute the most important single remedies in the armamentarium of pure dermatology; but the author also points out their dangers in unskilled hands, and expresses the view that every physician who employs these remedies should have a thorough training. The chapters on x-ray and radium dermatitis place on record all that is at present known concerning this condition, and the possibility of idiosyncrasy to radiations is discussed. In considering the action of radiations on pathological tissues it is suggested that too much prominence has been given to the supposed stimulating effect of irradiation on malignant neoplasms. The main portion of the book deals successively with the various skin conditions in which either x rays or radium, or both, can be effectively used. Each disease is considered by itself, and the numerous illustrations, which are exceedingly good, well chosen, and well reproduced, add considerably to the value of the letterpress. Following each chapter is a very complete bibliography, and there is a well printed and complete index. The exact dose of either x rays or radium, the exact method of application found to be the most suitable, filtration, and all the little details of technique are fully and plainly described. The author claims that the book is only written for the beginner, but expresses the hope that others will find it useful. It would be fair to say that this is a very modest statement. The book goes much further than this. It is one which every skin specialist should thoroughly digest, whether he has personal knowledge of the manner of application of rays or not; in addition, the radiologist who has to carry out the actual treatment of many skin conditions will find in it valuable information, useful illustrations, and many hints on technique. As a book of reference its construction is such that it should be of much value.

A book entitled *x-ray diagnosis for physicians and students*, was published by Dr. FRITZ MUNK of the Berlin University in 1914; a second edition⁴ has now appeared.

³ Food and the Principles of Dietetics. By Robert Hutchison, M.D., F.R.C.P. Fifth edition. London: E. Arnold, 1922. (Demy 8vo, pp. xx + 610, 33 figures, 5 plates. 2s. 6d.)
⁴ X Rays and Radium in the Treatment of Diseases of the Skin. By G. M. MacKie, M.D. London: Henry Kimpton, 1922. (Med. 8vo, pp. xi + 602, 259 figures. 4s. net.)
⁵ Grundriss der gesamten Röntgen-diagnostik innerer Krankheiten für Ärzte und Studierende. By Dr. Fritz Munk. Second edition. Leipzig: Georg Thieme, 1922. (Demy 8vo, pp. viii + 277; 185 figures. M 122.)

Following a short introductory chapter on physics and technique the main portion deals successively with the heart, the lungs, the gastro-intestinal tract, including the liver and gall bladder, the pancreas, and the kidneys; it concludes with a somewhat incomplete chapter on pathological processes affecting bones. The illustrations, which are numerous, vary considerably in merit; some are quite good, others—and this especially applies to those of the stomach—are very poor, and many are badly reproduced. The literature, which is referred to in a few pages at the end, is entirely German and Austrian, and there is no reference to any work done elsewhere. As a whole the book is merely a compilation; it contains nothing original, and there are many omissions. It may be of use to the German student or physician who wishes to get some idea of the scope and possibilities of x-ray diagnosis, but it hardly appears likely to appeal to British readers from this point of view, or as a book of reference.

In the book on x-ray diagnosis of pathological conditions of the stomach, by Drs. FAULHABER and KATZ,⁹ the shape, size, situation, tone, and motor functions of the normal organ are first discussed along the usual, more or less stereotyped, lines; the nomenclature suggested by Holzknecht, Grödel, and Forssell is employed. Chapters on gastroparesis and atony are illustrated by diagrams which are intended to represent these conditions, but some do not appear to be correct for either. There is no doubt that considerable confusion exists both amongst physicians and radiologists as to what is in fact gastroparesis, and the boundary line between what is normal and what is definitely gastroparesis still remains to be decided. Pyloric stenosis is discussed in nine pages, and there is a rather more elaborate chapter on ulcer under the headings of simple, callous, and penetrating; a chapter on carcinoma brings the book to a conclusion. The illustrations throughout are diagrammatic, but at the end are a dozen reproductions of somewhat indifferent radiographs. There is no index and no bibliography.

Mr. CHADWICK's little book on *Radioactivity and Radioactive Substances*¹⁰ is a short and clearly written account of a highly important branch of chemical study. It is meant for the general reader, and is as free as possible from mathematical formulae and terms unintelligible to the average person. It contains chapters on such subjects as the nature and measurement of radio-activity, ionizations, the various radiations emitted by radio-active substances, radium itself, and some of the general conclusions to which these studies have led. The book may be recommended to all in search of a short and lucid account of radioactivity.

EXERCISES FOR THE MAIMED.

The Handbook for the Limbless, recently reviewed in our columns, describes exercises practised at St. Thomas's Hospital and Roehampton by those who have lost lower limbs. In the north of England, Dr. F. A. HORT, the Administrator of the Ministry of Pensions Hospital, Chester Road, Sunderland, has published a pamphlet entitled *New Legs for Old*, which is intended, as is stated in the foreword, to be useful to those ex-service men who have lost one or both legs. It consists essentially of a description of a series of eight exercises, illustrated by the author with spirited sketches, which although they do not profess to be technically perfect, are at least illuminating, and in most cases may be taken as showing the cheerful enthusiasm with which the maimed man should undertake his tasks. Unfortunately the first of the series is rather discouraging. The pensioner who is being made to do knee bending appears to be filled with horror by the prospect. The lower jaw is protruded, the risus sardonius is well developed, and his hair stands on end. Probably he is meant for an awful warning, which has obviously been successful, for his seven successors appear to be quite pleased with life. All these exercises are intended to be performed by pensioners wearing their artificial limbs. The eight exercises are described as "Eltringham's Exercises," and are those recommended by Mr. T. Eltringham, Physical Instructor at the Ministry of Pensions Hospital, Sunderland. They appear to us to be well adapted to their purposes.

⁹ *Die Röntgendiagnostik der Magenkrankheiten*. By Drs. M. Faulhaber and L. Katz. Halle a. S.: Carl Marhold. 1922. (Med. 8vo, pp. 112; 51 figures, 2 plates. M. 17.)

¹⁰ *Radioactivity and Radioactive Substances*. By J. Chadwick, M.Sc., Ph.D. With Foreword by Sir E. Rutherford, D.Sc., LL.D., F.R.S. London: Sir I. Pitman and Sons, Ltd. 1921. (Pott 8vo, pp. viii + 111; 32 figures. 2s. 6d. net.)

Dr. Hort writes in Chapter I of the restoration of muscular capacity as one of the objects of the exercises. It is much to be regretted that so many who had to undergo amputation were allowed to use crutches long after they should have been wearing temporary peg legs with gypsium or fibre sockets; such pegs should in most cases be used as soon as the flaps are firmly united. Not only would muscular wasting thereby be avoided, but the tendency to put on weight, which has been a serious handicap to many men would be diminished.

We learn from the *Sunderland Echo* of January 19th that artificial limb-making is carried on by the pensioners in the occupational treatment workshops of the hospital where an exhibition and sale of work took place and athletic sports were held for men wearing artificial limbs; some of these artificial limbs had been made by patients in the hospital from the designs of Dr. F. A. Hort, "the originals having been exhibited in the war collection of the Royal College of Surgeons in London in 1917."

NOTES ON BOOKS.

WE have received the seventh edition of the book on *Practical Physiological Chemistry*,¹¹ by Professor HAWK, of Philadelphia. It contains a vast amount of information of a sort bearing on practical physiological work. Beginning with the subject of enzymes, it contains chapters on carbohydrates, proteins, nucleic acids and fats; the processes of salivary, gastric, pancreatic, and intestinal digestion; bile putrefactive products and faeces; the blood, milk, and various tissues; and the urine, which receives particular full treatment. In addition there are chapters on acids and metabolism that should be particularly useful as up-to-date summaries of our knowledge upon subjects that are engaging a great deal of attention at the present time. The book is well written, and contains a number of excellent coloured plates and illustrations, an appendix on the reagents and solutions used in the physiological laboratory, and a good index. It may be warmly commended to the attention of teachers and students of both physiology and medicine.

The second edition of Professor DENNETT's *Simplified Infant Feeding*¹² is a book for general practitioners of medicine who wish for a textbook dealing with the recurrent problems presented by mothers and nurses. It gives a full account of the subject in all its practical aspects, with particular reference to infantile indigestion. The author incorporates in the text notes of eighty cases illustrating various points he wishes to emphasize, and these form a most admirable aid for the reader. The book is full of practical directions, and may be recommended to all in search of a useful handbook on the subject of infant feeding.

The fourth edition of Mr. BENNETT's *Materia Medica and Pharmacy*¹³ provides medical students with a carefully written and condensed account of the drugs, chemicals and compound preparations of the *British Pharmacopoeia*, together with the diagnostic characters important for the recognition of the official drugs. Information as to the actions and uses of the drugs is given briefly, and various useful tables are incorporated in the volume. It may be recommended to those in search of a short handbook on the subject with which to deal.

Professor FISCHER, of Cincinnati, is known to pathologists in this country as a keen and original worker on the vexed question of the cause or causes of oedema. His recent book entitled *Soaps and Proteins*,¹⁴ is mainly an interesting study in colloid chemistry as applied to substances of these two classes, together with an account of the manufacture of soap considered from what may be called a colloid point of view. He remarks that oedema should be treated by giving salt by withholding water, Widal and his theory of dechlorination to the contrary notwithstanding. The book is well written and should be of interest to chemists and to chemically minded medical men.

¹¹ *Practical Physiological Chemistry*. By P. B. Hawk, M.Sc., Ph.D. Seventh edition, revised. London: J. and A. Churchill. 1921. (Med. 8vo, pp. xiv + 675; 192 figures, 6 plates. 24s. net.)

¹² *Simplified Infant Feeding, with Eighty Illustrative Cases*. By R. F. Dennett, B.S., M.D. Second edition, revised and enlarged. Philadelphia and London: J. B. Lippincott Co. (Med. 8vo, pp. 391; 14 figures. 21s. net.)

¹³ *Materia Medica and Pharmacy for Medical Students, with an Appendix on Incompatibility*. By R. R. Bennett, B.Sc. (Lond.), F.I.C. London: H. K. Lewis and Co., Ltd. 1921. (Fcap 8vo, pp. 287. 7s. 6d. net.)

¹⁴ *Soaps and Proteins: Their Colloid Chemistry in Theory and Practice*. By M. H. Fischer, M.D., with the collaboration of G. I. McLaughlin and Marion O. Hooker, M.D. New York: J. Wiley and Sons, Inc. London: Chapman and Hall, Ltd. 1921. (Med. 8vo, pp. 181; 114 figures. 4 dollars.)

SATURDAY, FEBRUARY 18TH, 1922.

THE GEDDES REPORTS.

TAXPAYERS will probably have read with a certain sense of disappointment the interim reports of the Geddes Committee appointed "to make recommendations to the Chancellor of the Exchequer for effecting forthwith all possible reductions in the national expenditure on supply services, having regard especially to the present and prospective position of the revenue." They will observe that the total reductions recommended amount to less than a fifth of the amount raised by the income tax alone, an amount greater than the whole revenue before the war, and that as to over two-thirds of the reductions, they are to be made in respect of two services only—defence and education, if, following the advice of the Committee, the Navy, Army, and Air be reckoned as one service. They will reflect that these services, probably the most influential, will fight tooth and nail in defence of their estimates, and they will note that on the very day the reports were published the Admiralty did in fact put out a memorandum the aggressive tone of which would appear to be approved by Mr. Churchill. In justice to the Committee it must be recollected that the instruction it subsequently received greatly limited the very wide terms of its original reference. It was told that national expenditure must be diminished by 175 millions, that in response to the Treasury circular of last May the departments had made reductions amounting together to 75 millions, and that it remained for the Committee to find ways of cutting down expenditure by another 100 millions. The reductions proposed by the departments themselves, it is pointed out, were not for the most part due to more economical administration or to curtailment of activities, but were, in fact, automatic and attributable to the fall of prices and wages, to windfalls, or to the cessation of special expenditure on services arising out of the war. The task of the Committee, coming in after full advantage had been taken of these circumstances, was therefore the more difficult. Taxpayers may find further justification for pessimism in a remark made about the Army and Air Force, but of general application; should the departments, it is said, act with energy the savings noted can be made or even exceeded, but "if delay occurs in giving effect to such of our major suggestions as the Government may approve, the saving cannot be realized in the coming year."

Another point which should be noted, since it throws light on the attitude of mind in which the Commissioners have approached their task, is the reluctance expressed in several places, chiefly in relation to scientific research, with which recommendations for reductions are made and the reasons given for making them. It is shown first with reference to the scientific services of the navy, where it is said: "We feel that if the country could afford it, probably the whole of the expenditure would be justified, but we are of opinion that in present circumstances some reduction must be made." Something of the same kind, but in even more sympathetic terms, is said with regard to certain public

health services—tuberculosis, maternity, and child welfare are specified. "There can be no question," the Committee reports, "as to the merits of the objects to be attained; there has, however, been a very large increase in this form of public expenditure since 1918-19, and, while we do not recommend reductions in this expenditure, we do feel that, having regard to the present financial position, the State's contribution, next year at any rate, should not be above the figure provided for the current year." The hope is indeed expressed that with falling prices and the greatly increased incentive to economy the local authorities "will be able still further to increase their beneficial work." The incentive to economy is the substitution for the percentage grant of a lump sum. The Committee condemns the system of the percentage grant even more strongly in its application to education than to public health. Under it the contribution of the State is a percentage of the total expenditure of the local authority. The vice of the system is declared to be that the local authority "which alone can really practise economy . . . loses much of its incentive to reduce expenditure, especially when the larger proportion is paid by the taxpayer through the Exchequer." There is no doubt much to be said for this, although the difficulty of fixing the lump sum is admitted. A capitation system is suggested. We could have wished the Committee had applied the principle to the University Grants; here a lump reduction from £1,500,000 to £1,200,000 is suggested, and the second report seems to imply a still greater reduction. It is to be feared that the appeals of the universities to which we have recently given publicity will be of little effect.

The recommendation which the Committee itself considers the most important of all it makes is that the Army, Navy, and Air Force should be brought together under one Minister of Defence, responsible for seeing that each force plays its part and is allotted appropriate responsibility for carrying out various functions. The Committee is of opinion that complete co-ordination in supply, transport, education, medical and other services would then be possible, and is sanguine enough to believe that no additional expense or extra Ministerial appointment need be involved, as the Minister and his staff could all be drawn from existing organizations.

With regard to the medical services it expresses the opinion that very heavy avoidable expenditure is involved in the maintenance of separate medical services of the Navy, Army, and Air Force, but seems to rest the case for unification—a favourite remedy of some reformers—mainly on what it regards as the need for a reduction in the number of army hospitals and their concentration. It recommends the mutual use of army or naval hospitals, whichever be the more economical in any particular area, and also that disabled war pensioners should be admitted into the military and naval hospitals indiscriminately, hoping in this way to effect a saving in the hospital charges of the Ministry of Pensions. We have no doubt that economy would result from the mutual use of hospitals where naval and military forces are stationed together—as, for example, Portsmouth and Devonport in England, and Malta and Gibraltar overseas. It would be difficult, however, to establish an organization by which the hospitals in the large military centres, such as those at Aldershot and Salisbury Plain, could be made available for naval sick, or on the other hand, by which the sick from these military centres could be treated in naval hospitals at Gosport or Devonport. In the large centres of military and naval activity, therefore, it seems certain that little, if any, advantage could be gained by the mutual use of military and naval hospitals. It is otherwise with the smaller centres, and in seaport towns such mutual use has for long been practised. Economy in this direction

however, is likely to be most effective at the naval and military stations of the Crown Colonies, such as Gibraltar, Malta, Singapore, Colombo, and Hong Kong, and not in the United Kingdom. We are afraid that when the matter comes to be looked into the recommendation for a drastic reduction of army hospitals will not prove as easy or effective as it may seem at first sight. It is true that the number of beds in time of peace is about 7,000, and that only 2,000 of these are constantly occupied, but the total is made up of numerous small local hospitals at regimental dépôts, which are more of the nature of detention wards; trivial cases are treated in barracks under what is called barrack hospital treatment. When this change was made the policy was adopted of concentrating in central hospitals, if necessary at some distance from the barracks, those cases which required serious hospital treatment. Under the advice of the Army Medical Advisory Board this policy of concentration of army hospitals had before the war become the recognized policy of the Army Council.

The chief questions, however, that arise in considering a unified medical service for the Forces are those which concern unity of command, autonomy of the medical services, and their training; closely allied to these are the preparation of the medical services in peace for their duties in time of war. There is still a tendency in the lay mind to regard medical services as concerned with the treatment of diseases and injuries only, whereas it has only been by long and careful preparation, organization, and training that the medical services in war have been able to cope with the varied and manifold duties thrown upon them. The question arises how in a unified medical service the preparation, training, and organization for duties with the navy and for duties with the army are to be distinguished. The requirements are different, and, if in this respect alone, it is to be expected that a cleavage into naval and military medical services would be experienced soon after the creation of a unified service.

But, while it is not quite clear to what extent a unified medical service and the mutual use of naval and military hospitals would result in a real economy or would be free from the danger of inadequate preparation of the two services for war, there can be no doubt that the vacant accommodation in the larger military hospitals might be made available for patients at present admitted to hospitals of the Ministry of Pensions. The admission, however, of disabled war pensioners indiscriminately to military hospitals opens up the question whether, for example, treatment in any but specialized and organized hospitals for the orthopaedic class or the neurological class of pensioner would be for the benefit of the men. From the financial aspect alone it will be asked whether the policy proposed might not lead to such a prolongation of invalidism as to minimize to a great extent the economy effected by closing down hospitals of the Ministry of Pensions. The answer to this is that sections of existing military hospitals could be organized in the same way under specialists; but it would have to be shown that there is accommodation constantly vacant in the larger military hospitals. The smaller military hospitals of 10, 20, or 30 beds would be useless for the purpose, and there are only some ten army hospitals which on a peace basis of equipment have 200 or more beds each, and only seven with less than 200 but over 100 beds. By far the greater number of military hospitals are small garrison or dépôt hospitals. With the present number of patients under treatment by the Ministry of Pensions, therefore, the Committee's proposal does not seem feasible from the point of view of accommodation alone, irrespective of specialist treatment.

There is one point which must not be overlooked; it is probably the most important of all. A unified medical

service for the Forces cannot be worked unless there is unity of control. The mutual use of hospitals will not achieve such a purpose; and there is nothing more liable to lead to friction, incompetency, and disaster than dual control in the same sphere of activity. It is needless to recount examples of this. They are written large throughout the pages of history; and unless all the services are united under one Ministry, with one head of its medical department, dual control will be the inevitable and disastrous result.

The section of the report dealing with National Health Insurance begins by pointing out that the estimate for 1922-23, though over a million less than that for 1921-22, is more than twice the expenditure for 1914. Of the million saved nearly the whole is attributed to the reduction in the capitation fee accepted by the members of the medical profession working under the insurance scheme. The Committee, after noting this patriotic act, goes on to point out that the State has progressively accepted additional burdens and additional costs and has not reaped any benefit from the windfalls which accrued to the funds of approved societies as a consequence of the war. It recommends that such burdens should be transferred to the insurance organizations, where they might be compensated for by improvement in the actuarial position; it also advises an increase in contributions to meet the additional costs of medical and other benefits now borne by the State in excess of its proper share of two-ninths. It advises an increase in the weekly contributions of employer and insured person by $\frac{1}{2}$ d. in each case, and the Ministry of Health is understood to have in hand a bill to authorize this. The general effect of putting into force the suggestions enumerated would be to relieve the taxpayer and saddle the insured person and employer with the cost of any additions to the original scheme. The tendency has been, whenever any extension or improvement was introduced, to meet the cost by an additional grant from the Exchequer. This apparently must now cease. The probability is that if the approved societies undertake increased monetary responsibilities they will be less amenable to those State restrictions which they accepted more or less meekly when accompanied by financial help. The position is one which the medical profession will have to watch.

Two other specific economies are discussed in this section of the report. In a passage dealing with the medical referee consultants they are spoken of "as to some extent a luxury," costing, on a reduced estimate, £85,000 a year, though it is hoped to recover £7,500 from the societies by way of fees. No doubt it is true that the insurance system could get on without the referee consultants, but if by speaking of them as a luxury it intended to convey that they are unnecessary, or that in the long run their abolition would be a saving, the dictum is open to serious question. The suggestion that the societies might revert to the old plan of employing their own referees will not be well received by insurance practitioners, who found the old plan very unsatisfactory and a source of continual friction. Almost from the commencement of the insurance system the profession, through the British Medical Association and later through the Panel Conference, urged that independent referees were needed, and since the appointment of the regional officers the referee system has worked very smoothly. It will, we believe, be a mistake to revert to the old system. The Committee also proposes that the index clearance branch, costing £30,000 a year, should be abolished. At the commencement of the system the duty of furnishing to doctors correct lists of the insured persons for whom they were responsible was placed on the Insurance Committees. These were supposed to get their information from the approved societies, but they proved totally incompetent to provide it. After experience

CURRENT NOTES.

The Newcastle Meeting.

Dinner to Mr. R. J. Willan and Dr. George Hall.

A very enjoyable function took place at the Station Hotel, Newcastle-upon-Tyne, on February 3rd, when Mr. R. J. Willan and Dr. George Hall (respectively Honorary Local General Secretary and Honorary Local Treasurer of the 1921 Annual Meeting of the British Medical Association) were honoured by a complimentary dinner. There was a large attendance, which would have been larger still but for the inclemency of the weather and the influenza epidemic. To the regret of all, Dr. Hall was himself a victim of influenza and unable to be present. The President of the Association, Professor David Drummond, presided, and in the course of the evening, on behalf of numerous subscribers, presented Mr. Willan with a handsome gift in the shape of a grandfather's clock, which bore the following inscription:

"Presented to R. J. Willan, Esq., M.V.O., O.B.E., M.S., F.R.C.S., in recognition of his invaluable services as Honorary Local General Secretary of the British Medical Association's Annual Meeting, held in Newcastle-upon-Tyne, July, 1921."

Dr. R. A. Bolam (Chairman of Council) proposed the toast of "Our Guests," which was replied to by Mr. Willan, who in doing so reviewed in some detail the activities of the various committees in their efforts to ensure a successful meeting. The result of all these endeavours was, as probably everyone recognizes, an exceptional success, and the Newcastle meeting will long be remembered as a model of organization. Several local members of the profession contributed to the musical programme, and were warmly complimented by Professor Sir Thomas Oliver in proposing a vote of thanks to them. Altogether the evening was a most pleasant one, and will be remembered as one of the most agreeable functions in connexion with the British Medical Association in the neighbourhood.

Fee for Notification of Infectious Diseases.

It is necessary to return once more to the question of the fee for notification of infectious diseases. A correspondent wrote to say that in reply to a letter concerning the correctness of the amounts paid to him the clerk to the urban district council told him that he was mistaken in assuming that the fee was 2s. 6d. The clerk went further than that, and stated that the Order in Council restoring the fee to its pre-war value had been cancelled by a further Order. A letter was accordingly addressed to the Ministry of Health stating that the British Medical Association had good reason for believing that the payment of the restored fee was by no

means universal. A copy of the clerk's statement was enclosed, and the Ministry was asked if any steps could be taken to bring about uniformity of action. The reply from the Ministry is as follows: "I am directed by the Minister of Health to state that steps will be taken at an early date to remind local authorities that as from September 1st, 1921, the fee payable to medical practitioners for the notification of cases of infectious disease occurring in their private practice reverted to 2s. 6d."

Pay of I.M.S. Officers in Civil Employ.

The Naval and Military Committee recently had under consideration a statement by an officer in the Indian Medical Service that as recently as February, 1921, not only had the increases in pay to I.M.S. officers in civil employ not been paid, but that he had been told that he was not entitled to the particular sum he had claimed because Army Instruction (India) No. 613 sanctioning the increased rates of pay was published only on August 17th, 1920. The increase in pay to I.M.S. officers in military employment was published in July, 1920, and made retrospective to January 1st, 1920, and there is no doubt that the civil officers should have received their increase from the same date. The Committee felt that this ruling, if allowed to pass unchallenged, cut at the root of the recent concessions which had been gained after so prolonged a struggle, and decided to call the attention of the Secretary of State for India to the matter without delay. Accordingly copies of the correspondence were sent to the India Office, and a reply was received to the effect that the officer appeared to be entitled to the sum claimed, and that the correspondence had been forwarded to the Government of India for disposal. This correspondent now writes to say that he has been informed that his emoluments for the period named will be readjusted in accordance with an Army Instruction (India) which is being issued. It is understood that this readjustment will affect the pay of an appreciable number of I.M.S. officers.

Medical Fees for Attendance at Maternity and other Centres in Scotland.

The Scottish Committee of the British Medical Association has received from the Board of Health a reply to its representation that a fee of £1 ls. per session should be approved in cases where the session does not normally exceed one hour. The Board state that they cannot recognize a uniform fee or scale of fees, and point out that the fixing of the fee is a matter primarily for local settlement between the local authority and the doctor appointed as medical officer to the Centre. When it is reported that the sum proposed to be allowed is inadequate to secure a sufficient service the Board are willing to consider the special circumstances. Bearing in mind that the doctor who undertakes such work is expected to attend regularly at a fixed hour, and that the work is of a special character, the Committee again strongly advises medical practitioners not to accept a fee of less than £1 ls.

Association Notices.

TABLE OF DATES.

Mar. 15, Wed.	Branch Reports for 1921 due to Head Office on or before this date.
April 1, Sat.	Nomination papers available at Head Office for election of 24 Members of Council for 1922-23, by grouped Home Branches.
April 26, Wed.	Council Meeting, 429, Strand, at 10 a.m.
April 29, Sat.	Last day for receipt at Head Office of Independent Motions for Annual Representative Meeting Agenda, as to policy, Articles or By-laws (By-law 40).
May 6, Sat.	Annual Report of Council appears in SUPPLEMENT.
May 8, Mon.	Last day for receipt at Head Office of Nominations, by a Division or not less than 3 Members, for election of 24 Members of Council by grouped Home Branches for 1922-23.
May 13, Sat.	Publication in SUPPLEMENT of list of nominations for election of 24 Members of Council by grouped Home Branches for 1922-23. Voting papers for election of 24 Members of Council by grouped Home Branches posted from Head Office to Members of groups where there are contests.
May 27, Sat.	Last day for receipt at Head Office of voting papers for election of 24 Members of Council by grouped Home Branches. (Where there are contests.)
June 3, Sat.	Publication in SUPPLEMENT of results of Council elections by grouped Home Branches.
June 10, Sat.	Nomination papers available, at Head Office, for election of 12 Members of Council by grouped Home Representatives.
June 14, Wed.	Council Meeting, 429, Strand, at 10 a.m.
June 23, Fri.	Last day for election of Representatives and Deputy-Representatives.
June 24, Sat.	Supplementary Report of Council appears in SUPPLEMENT.
June 30, Fri.	Last day for receipt at Head Office of notification of election of Representatives and Deputy-Representatives.
July 7, Fri.	Last day for receipt at Head Office of Amendments and Riders for Annual Representative Meeting Agenda.
July 21, Fri.	Annual Representative Meeting, Glasgow, 10 a.m.

ALFRED COX,
Medical Secretary.

BRANCH AND DIVISION MEETINGS TO BE HELD.

BATH AND BRISTOL BRANCH.—The fourth general meeting of the Bath and Bristol Branch will be held at the Red House, Bath, on Wednesday, February 22nd, at 8 p.m., when Sir J. Thomson Walker will give an address on Recent Advances in Diagnosis and Treatment in Urinary Surgery. It is proposed that the members of the Branch shall dine together before the meeting, provided a sufficient number express a desire to do so. Members proposing to attend should notify Dr. F. G. Thompson, 28, Circus, Bath, without delay.

ESSEX BRANCH: MID-ESSEX DIVISION.—The Medical Secretary, Dr. Alfred Cox, will speak at the Bell Hotel, Chelmsford, on Wednesday, February 22nd, at 3.30 p.m., on the subject, "How the British Medical Association might be of more use to medical men." Questions will be invited at the end of the address. Non-members as well as members are cordially invited.

METROPOLITAN COUNTIES BRANCH: WESTMINSTER DIVISION.—Nominations for the election of Representatives on the Council and Representative Body, and for members of the Executive Committee of the Division, should be sent to the Honorary Secretary, Dr. F. D. Bennett, 18, Savile Row, W.1.

METROPOLITAN COUNTIES BRANCH: WILLESDEN DIVISION.—A meeting of members and non-members will be held in St. Andrew's Church Hall at 8.30 p.m. on Tuesday, February 21st. Agenda: Meet medical candidates for municipal election (Drs. W. Lock, G. W. R. Skeue, D. V. Muller, J. B. Dunning). Proposed V.A.D. clinic in Willesden. Parliamentary election. Revision of British Medical Association constitution, etc. (SUPPLEMENT, December 24th, p. 237).

STAFFORDSHIRE BRANCH.—A meeting of the session will be held at the Swan Hotel, Stafford, on Thursday, February 23rd, at 4 p.m. Agenda: Exhibition of living cases, pathological specimens, etc. Papers: (1) Dementia Praecox, by Dr. Farran-Ridge; (2) Epidemic Encephalitis, by Dr. E. J. Bradley. Lantern demonstration of diseases of stomach, duodenum, bladder, etc., by Mr. F. N. Cookson. Dinner at 6.30 p.m., charge 10s.

YORKSHIRE BRANCH: BRADFORD DIVISION.—A meeting of the Bradford Division will be held at the Great Northern Victoria Hospital on Wednesday, February 22nd, at 8.30 p.m., when Dr. G. C. Anderson, Deputy Medical Secretary, will give an address on The Activities of the British Medical Association; the Advantages of being a Member.

EDUCATION AUTHORITIES AND THE SCHOOL MEDICAL SERVICE.

In a leading article in the JOURNAL of January 21st (p. 113) it was stated that the British Medical Association and the Society of Medical Officers of Health had asked the Minister of Health to receive a deputation to discuss with him the relation of the Ministry of Health and the Board of Education to the medical inspection and treatment of school children. Sir Alfred Mond is receiving the deputation on Friday morning, February 17th, and an account of the proceedings will appear next week.

The following letter was sent by the British Medical Association on January 28th to the Minister of Health:

It has been brought to the notice of this Association that the Directors of Education are making a strong effort to secure that all the activities of school medical officers shall be supervised by, and under the control of, the chief education officers. The British Medical Association desires in the most emphatic manner to express its opinion to the Minister of Health that this movement, if not stopped, will have the most mischievous effects on the School Medical Service, and through it on the children for whose health the Minister of Health is directly responsible.

Under Section 3 (1) (d) of the Ministry of Health Act, 1919, all powers and duties of the Board of Education with respect to the medical inspection and treatment of school children and young persons were transferred to the Ministry of Health from the Board of Education. It is true that by a proviso to that Section the Minister of Health was empowered to make arrangements with the Board of Education "respecting the submission and approval of schemes of local education authorities and the payment of grants to local education authorities so far as such schemes and payment relate to or are in respect of medical inspection and treatment." The Association well remembers the resistance of the then President of the Local Government Board, supported by the President of the Board of Education, to the transfer of the powers relating to medical inspection and treatment of school children from the Education Department to the Ministry of Health. This resistance was met with almost unanimous disapproval on the part of the Committee which was considering the Bill, and the British Medical Association did what it could to strengthen the hands of those members of Parliament who were determined that these medical functions should be put under the care of the Ministry of Health and made part of a great national health system.

It has always been understood that the arrangements made between the Ministry of Health and the Board of Education were temporary, and would be brought to an end as soon as the Ministry was in a position to take the duties over. It was therefore with some concern that the Association found that in the Education Act, 1921, various Sections (16, 18, and 116 (6)) continued the proviso by means of which the Minister of Health is empowered to make arrangements with the Board of Education regarding schemes for the medical inspection and treatment of school children. If nothing else had happened the Association would probably have taken no action, assuming that the reasons which led the Minister to leave these matters temporarily in the hands of the Board of Education still held good. But the Association of Directors and Secretaries for Education has issued a memorandum (no doubt known to the Ministry of Health) on the relations between the School Medical Service and general education administration, in which the most extreme claims for domination over a service which is primarily medical and not educational are made by education officers, and therefore this Association feels that it is time to make a determined protest.

This protest is made because the British Medical Association believes that all the medical services of the country should be co-ordinated and should be directly under the control of the Ministry of Health. It views with concern even a temporary relegation of some of these duties to other Ministries, and in view of the dangers illustrated by what is happening in the Education Medical Service it strongly urges the Minister to take these duties under his direct control at the earliest possible moment. If that moment must for some reasons be deferred, the Association would ask the Minister to make it plain to Education Authorities and to their Administrative Officers that the School Medical Service is a medical service, and that the Minister of Health will reserve his right to refuse sanction to schemes which allow the action of Education Officers to affect the proper co-ordination of Medical Services or the efficiency of the School Medical Service as a health service, or to intercept the advice given to an authority by school medical officers.

The Association has been in consultation with the Society of Medical Officers of Health, and both bodies feel so concerned with the dangers of the present situation that they would respectfully request the Minister to meet a joint deputation from the two bodies at an early date.

British Medical Association.

NINETIETH ANNUAL MEETING, GLASGOW, JULY 25th, 26th, 27th, & 28th, 1922.

Patron: HIS MAJESTY THE KING.

President: DAVID DRUMMOND, C.B.E., M.A., M.D., D.C.L., Vice-Chancellor and Professor of the Principles and Practice of Medicine, University of Durham.

President-Elect: Sir WILLIAM MACFARLANE, C.B., D.Sc., D.C.L., M.D., F.R.S., Regius Professor of Surgery, University of Glasgow, one of the Honorary Surgeons to H.M. the King in Scotland.

Chairman of Representative Meetings: R. WALLACE HENRY, B.A., M.D.

Chairman of Council: ROBERT ALFRED BOLAM, M.D., M.R.C.P.

Treasurer: GEORGE ERNEST HASLIP, M.D.

PROGRAMME.

The President will give his address to the Association on Tuesday, July 25th, at 8 p.m.

The REPRESENTATIVE MEETING will begin on Friday, July 21st, at 10 a.m., and be continued on the following three week-days.

The STATUTORY ANNUAL GENERAL MEETING will be held on July 25th, at 2 p.m., and the adjourned General Meeting at 8 p.m.

The Annual Dinner of the Association will take place on July 27th, at 7.15 p.m.

The official Religious Service will be held in Glasgow Cathedral on July 25th, at 5.15 p.m., and Mass will be celebrated in St. Andrew's Roman Catholic Cathedral on July 27th, at 9.15 a.m.

The Conference of Secretaries will be held at 2 p.m. on July 25th, and the Secretaries' Dinner will take place in the evening at 6.30.

The Pathological Museum and the Annual Exhibition of surgical instruments and appliances, foods, drugs, and books will open on July 25th.

The Popular Lecture will be delivered by Professor John Graham Kerr, F.R.S., on July 28th, at 7.30 p.m.

Saturday, July 29th, the last day of the meeting, will be set apart for excursions to places of interest in the neighbourhood.

THE SECTIONS.

The Scientific Sections will meet from 10 a.m. to 1 p.m. for papers and discussions. Laboratory and clinical demonstrations in connexion with the work of the Sections will be given in the classrooms of the University on the afternoons of Wednesday, Thursday, and Friday, July 26th, 27th, and 28th.

The following Sections meet on three days—Wednesday, Thursday, and Friday, July 26, 27, and 28.

MEDICINE.

President: Professor THOMAS KIRKPATRICK MONRO, M.D., F.R.C.P.S.

Vice-Presidents: JOHN M. COWAN, M.D., F.R.F.P.S., D.Sc.; S. ARCHIBALD E. GARROD, K.C.M.G., M.D., F.R.C.P.; F.R.S.; GEORGE HALL, C.M.G., M.D., M.R.C.P.; C. O. HAWTHORNE, M.D., F.R.C.P.; JOHN HAY, M.D., F.R.C.P.

Honorary Secretaries: ADAM PATRICK, M.D., F.R.F.P.S., 16, Buckingham Terrace, Glasgow; H. LETHBRIDGE, M.D., F.R.C.P., 39, Devonshire Place, London, W.1.

NEUROLOGY AND PSYCHOLOGICAL MEDICINE.

President: GEORGE A. EASTENBROOK, M.D., F.R.C.P. Edin., F.R.C.P., C. C. EASTENBROOK, M.D., F.R.C.P., JACOBSON, M.B., F.R.F.P.S.; Sir JAMES PURVES STEWART, K.C.M.G., C.B., M.D., F.R.C.P.

Honorary Secretaries: HILDERED CARLILL, M.D., M.R.C.P., 146, Hanley Street, London, W.1; D. K. HENDERSON, M.D., F.R.F.P.S., 17, Whittingham Drive, Glasgow.

OPHTHALMOLOGY.

President: A. S. PERCIVAL, M.B., M.R.C.S.

Vice-Presidents: A. J. BALLANTYNE, M.D., F.R.F.P.S.; Sir WILLIAM T. LISTER, K.C.M.G., F.R.C.S.; JOHN ROWAN, M.B., F.R.F.P.S.

Honorary Secretaries: PERCIVAL J. HAY, M.D., 350, Glossop Road, Sheffield; W. H. MANSON, M.D., F.R.F.P.S., 17, Royal Terrace, Glasgow.

PATHOLOGY.

President: Professor ROBERT MUIR, M.D., F.R.C.P. Edin., F.R.S.

Vice-Presidents: J. S. C. DOUGLAS, M.D.; Professor JOHN SHAW DUNN, M.D.; ARCHIBALD LEITCH, M.B., Ch.B.; Professor JOHN H. TEACHER, M.D., F.R.F.P.S.

Honorary Secretaries: JOHN ANDERSON, M.B., C.M., "Westerhill," St. Bride's Road, Newlands, Glasgow; ROBERT DONALDSON, M.D., F.R.C.S. Edin., St. George's Hospital, London, S.W.1.

SURGERY.

President: Professor H. ALEXIS THOMSON, C.M.G., M.D. Ed., F.R.C.S.

Vice-Presidents: JAMES BERRY, F.R.C.S.; Sir KENNEDY DALZIEL, M.B., F.R.F.P.S.; A. ERNEST MAYLARD, M.B., F.R.F.P.S.; G. GREY TURNER, M.S., F.R.C.S.; R. J. WILLAN, M.V.O., O.B.E., M.S., F.R.C.S.

Honorary Secretaries: J. A. C. MACFARLANE, M.B., F.R.F.P.S., 3, Woodside Crescent, Charing Cross, Glasgow; JOHN PATRICK, M.B., F.R.C.S. Ed., 9, Newton Place, Glasgow; H. S. SOUTTAN, C.B.E., M.Ch., F.R.C.S., 58, Queen Anne Street, London, W.

The following Sections will meet on two days.

DERMATOLOGY.

President: H. LESLIE ROBERTS, M.D., C.M.

Vice-Presidents: A. M. H. GRAY, C.B.E., M.D., F.R.C.P.; G. H. LANCASHIRE, M.D.; Professor J. G. TOMKINSON, M.D.

Honorary Secretaries: WM. HERBERT BROWN, M.D., 20, Park Circus, Glasgow; HALDIN DAVIS, M.B., F.R.C.S., 17, Cavendish Place, London, W.1.

DISEASES OF CHILDREN.

President: Sir HERBERT F. WATERHOUSE, M.D., F.R.C.S.

Vice-Presidents: LEONARD FINDLAY, M.D., F.R.F.P.S.; ROBERT HUTCHISON, M.D., F.R.C.P.; ALAN MCLENNAN, M.B., C.M.; R. H. A. WHITELOCKE, M.D., F.R.C.S.

Honorary Secretaries: GEOFFREY BOURNE, M.D., M.R.C.P., 153, Harley Street, London, W.1; G. B. FLEMING, M.B.L., M.D., 15, Lynedoch Crescent, Glasgow.

MICROBIOLOGY (INCLUDING BACTERIOLOGY).

President: ROBERT MACNEIL BECHANAN, M.B., F.R.F.P.S.

Vice-Presidents: JOHN ANDERSON, M.A., B.Sc., Professor HY. ROY DEAN, M.D., F.R.C.P., Sir WM. B. LEISHMAN, K.C.M.G., C.B., F.R.S.

Honorary Secretaries: S. PHILLIPS BEDSON, M.D., Lister Institute, Chelsea, London, S.W.; J. L. BROWNIE, M.D., D.P.H., 23, Hamilton Park Terrace, Glasgow.

OBSTETRICS AND GYNAECOLOGY.

President: Professor EWEN J. MACLEAN, M.D., M.R.C.P.

Vice-Presidents: H. RUSSELL ANDREWS, M.D., F.R.C.P.; Professor J. M. MUNRO KERR, M.D., F.R.F.P.S.; Professor LOUIS MCILROY, M.D., D.Sc.; E. FARQUHAR MURRAY, M.D., F.R.C.S.

Honorary Secretaries: S. J. CANERON, M.B., F.R.F.P.S., 39, Lynedoch Street, Charing Cross, Glasgow; W. D. MACFARLANE, M.B., F.R.F.P.S., 17, Woodside Crescent, Glasgow; H. G. TAYLOR, M.B., 15, Cavendish Place, London, W.1.

PHYSIOLOGY.

President: Professor J. A. McWILLIAM, M.D., C.M., F.R.S.

Vice-Presidents: Professor EDWARD MELLANBY, M.D.; Professor D. NOEL PATON, M.D., F.R.C.P., F.R.S.

Honorary Secretaries: GEORGE GRAHAM, M.D., F.R.C.P., 37, Queen Anne Street, London, W.1; W. F. SHANKS, M.B., Ch.B., Physiological Institute, University of Glasgow.

PUBLIC HEALTH.

President: A. K. CHAMBERS, M.D., F.R.F.P.S., D.P.H.

Vice-Presidents: R. J. REECE, C.B., M.D., M.R.C.P., D.P.H.; F. E. FREMANTLE, O.B.E., M.P., M.B., F.R.C.P., D.P.H.; HAROLD KERR, O.B.E., M.D., D.P.H.

Honorary Secretaries: R. S. FULLERTON, M.D., F.R.F.P.S., Sanitary Chambers, Glasgow; J. J. PATTERSON, M.D., The Gaitthall, Maidenhead.

The following Sections will meet each on one day.

ANATOMY.

President: Professor ALEXANDER MACPHAIL, M.B., C.M., F.R.F.P.S.
Vice-Presidents: J. C. BRASH, M.C., M.B., Ch.B.; Professor J. T. WILSON, M.B., F.R.S.
Honorary Secretaries: Professor JAMES BATTERSBY, F.R.C.S., F.R.F.P.S., 616, Great Eastern Road, Glasgow; Professor JOHN GRAHAM, F.R.F.P.S., 351, Renfrew Street, Glasgow.

ANAESTHETICS.

President: W. J. MCCARDIE, M.B., B.Ch.
Vice-Presidents: JAMES PATON BOYD, M.B., F.R.F.P.S.; L. MABEL RENWICK CAMPBELL, M.B., Ch.B.
Honorary Secretaries: H. PRESCOT FAIRLIE, M.D., 19, Bute Gardens, Glasgow; HUBERT PINTO-LEITE, M.R.C.S., L.R.C.P., 24, Fellows Road, South Hampstead, London, N.W.3.

INDUSTRIAL DISEASES AND FORENSIC MEDICINE.

President: Professor JOHN GLAISTER, M.D., F.R.F.P.S., D.P.H., F.R.S.E.
Vice-Presidents: GODFREY CARTER, M.B., M.R.C.P.Edin., D.P.H.; WILLIAM LEDINGHAM RUNTON, M.B.; Sir WILLIAM H. WILLCOX, K.C.I.E., C.B., C.M.G., M.D., F.R.C.P.
Honorary Secretaries: Professor ANDREW ALLISON, M.B., F.R.F.P.S., D.P.H., St. Vincent Park, Paisley Road, W. Ibrox, Glasgow; JAMES R. KERR, C.B.E., Ch.M., The Pilkington Special Hospital, St. Helens, Laucs.

LARYNGOLOGY.

President: JOHN MCINTYRE, M.B., C.M., F.R.F.P.S.
Vice-Presidents: A. BROWN KELLY, M.D., F.R.F.P.S.; Sir ST. CLAIR THOMSON, M.D., F.R.C.P., F.R.C.S.
Honorary Secretaries: F. F. MUECKE, C.B.E., M.B., F.R.C.S., 36, Cavendish Square, London, W.; W. S. SYME, M.D., F.R.F.P.S., 11, Lynedoch Crescent, Glasgow.

MEDICAL SOCIOLOGY.

President: E. ROWLAND FOTHERGILL, M.B., B.S.
Vice-Presidents: CHARLES E. S. FLEMING, M.R.C.S., L.R.C.P.; JAMES HUDSON, M.D., C.M.; PETER MACDONALD, M.D.
Honorary Secretaries: ALEX. FORBES, M.B., C.M., Hillsboro' Lodge, Sheffield; DAVID McKAIL, M.D., F.R.F.P.S., 2, Morris Place, Monteith Row, Glasgow.

OTOLOGY.

President: ALBERT ALEX. GRAY, M.D., F.R.F.P.S.
Vice-Presidents: J. G. CONNAL, M.B., F.R.F.P.S.; W. F. WILSON, M.B.
Honorary Secretaries: F. J. CLEMINSON, M.Ch., F.R.C.S., 32, Harley Street, London, W.1; J. W. LEITCH, M.B., 6, Clairmont Gardens, Charing Cross, Glasgow.

RADIOLOGY.

President: LEONARD A. ROWDEN, M.B., C.M.
Vice-Presidents: E. P. CUMBERBATCH, M.B., M.R.C.P.; JAMES ROBERTSON RIDDELL, F.R.F.P.S.
Honorary Secretaries: P. HERMANAN-JOHNSON, M.D., 66, Harley Street, London, W.1; D. O. MACGREGOR, M.B., C.M., Langside Cottage, Langside, Glasgow.

TUBERCULOSIS.

President: Sir ROBERT W. PHILIP, M.D., P.R.C.P.Edin., F.R.S.E.
Vice-Presidents: JAMES CROCKET, M.D., D.P.H.; WM. HY. DICKINSON, O.B.E., M.B., D.P.H.
Honorary Secretaries: A. HOPE GOSSE, M.D., M.R.C.P., 75, Harley Street, London, W.; A. S. M. MACGREGOR, O.B.E., M.D., D.P.H., 488, Clarkston Road, Muirend, Cathcart, Glasgow.

Honorary Local General Secretary.

Dr. GEORGE A. ALLEN, 22, Sandyford Place, Glasgow, W.

Meetings of Branches and Divisions.

SOUTHERN BRANCH: PORTSMOUTH DIVISION.

A MEETING of the Portsmouth Division was held on February 1st at the Corner House, Commercial Road, Portsmouth. The question of an advertisement appearing recently in a lay newspaper inviting applications for an Honorary Consulting Staff to the Workhouse Infirmary was discussed, and it was resolved that the policy of the British Medical Association, as laid down by the Annual Representative Meeting of 1908, be adhered to—namely:

"That the Representative Meeting considers that the services of the profession should not be given gratuitously to patients who are maintained by public funds."

Dr. A. P. BEDDARD gave a lecture on chronic arthritis, and many questions were asked afterwards, to which he replied seriatim. The meeting was followed by a supper. The "Minster Singers" contributed to render the evening enjoyable. The attendance was somewhat curtailed owing to the prevailing influenza.

THE GEDDES REPORT ON NATIONAL EXPENDITURE.

PROPOSALS FOR ECONOMY.

THE First and Second Interim Reports of the Committee on National Expenditure, of which Sir Eric Geddes is chairman, were issued on February 10th. The other members of the Committee are Lord Inchcape, Lord Farrington, Sir J. Maclay, and Sir Guy Granet.

The terms of reference are "for effecting all possible reductions in expenditure on supply services." The Government departments, in response to a Treasury circular in May last year, have themselves proposed reductions amounting to 75 millions, and the aim of the Geddes Committee is to secure a further reduction of 100 millions. The recommendations in the reports now published would give total reductions of £75,061,875, and there remain to be dealt with 60 votes representing 100 millions of expenditure and various other matters outstanding. The "cuts" suggested come under the following headings:

	£
Navy	21,000,000
Army	20,000,000
Air	5,500,000
Education	18,000,000*
Health	2,500,000*
War pensions	3,300,000*
Trade group	538,000
Export credits	503,000
Agricultural group	855,000
Police and prisons	1,595,000
General group (24 votes)	102,000
* Additional savings on these Ministries	1,171,875
Total	£75,061,875

THE THREE FIGHTING SERVICES.

The Committee hold that full economy in the fighting services cannot be realized under existing conditions. There is overlapping and duplication throughout. In order fully to realize these economies the three forces must be brought together by the creation of a co-ordinating authority or Ministry of Defence. Complete co-ordination in supply, transport, education and other functions would then be possible. Subject to this suggestion for the future the Committee considered the three fighting services individually.

The Naval Estimates.

In a detailed statement they advise that the Naval Estimates for 1922-23 should be reduced from 81 millions to 60 millions, and that in a subsequent year lower estimates should suffice. The reductions in personnel involved would be 35,000 officers and men. This view is presented without taking into account large savings which might result from the Washington Conference proposals and from a possible reduction in capital and other ships in commission, and consequential saving in the provision of oil. Nor is any account taken of any reduction in pay or allowances which the Government might make, nor of any abnormal increase in the non-effective vote caused by reduction of the personnel transferred to the retired list. The various votes are next examined separately.

Under the heading "Hospital Ships" it is remarked that the Admiralty now have two, *Berbice* and *Maine*; the latter was bought recently, and is now being refitted. Before the war the Admiralty had only one. It is suggested that one or other should be sold.

Under the heading "Medical Establishments" comparative figures are given as follows:

	£
1913-14 audited expenditure	281,382
1921-22 net estimate	720,500
1922-23 net estimate	625,000

The report states that this vote, which does not include the naval medical personnel borne on Vote I, is more than double pre-war in amount, and that it is significant that medical and dental services for the Navy, which must necessarily be composed of men of a high standard of physical efficiency, cost, when the salaries of personnel on Vote I are included, roughly, £12 per head. This appears to the Committee to be an unduly high figure, but they say they have no individual item to comment upon. They hold, however, that in view of the present high costs everything possible should be done to combine the medical facilities on shore of the three fighting services, a matter in which very little has been effected hitherto. The reduced numbers of naval personnel which have been suggested would affect this vote. The Committee deal with the cost of the medical services under the Army Estimates.

The Army Estimates.

The Committee recommend that the Army Estimates for 1922-23 should be reduced from £75,197,800 to £55,000,000, and that in a subsequent year lower estimates should suffice.

The reduction in personnel involved would be 60,000 officers and men, without change in the number employed on foreign service.

The Committee make the following report on the Army Medical Services:

"The establishment of the Royal Army Medical Corps is increased from 4,460, costing £695,000 in 1914-15 to 5,535, costing £1,700,000 in 1922-23. Of the increases of 157 officers and 916 other ranks 94 officers and 163 other ranks are for the new Dental Corps. The remainder are stated to be due to provision for garrisons in Mesopotamia, Palestine, and on the Rhine. The total cost of all Army Medical Services is stated to be as follows:—

	Total Cost.	Per head of British and Colonial Troops.
	£	s d.
1914-15	1,340,000	7 13 8
1922-23	3,973,000	19 12 7

No comparative figures for 1922-23.

These figures are calculated under the new Army Cost Accounting System to cover the whole cost of the Service, including effective and non-effective pay and maintenance of medical staff, the maintenance of hospitals, the purchase of medicines, etc., and the hire of a hospital ship, and it cannot, therefore, be compared strictly with the Naval cost of £12 a head. Making all allowances, however, for this consideration, and the additional expenditure involved by conditions in the Middle East, the cost appears to us to be unduly high. The Army had no hospital ship before the war. The Navy had one and now has two. The Army hospital ship costs £172,000 per annum, and we suggest that combined use of the naval ship should be considered.

In this connexion we desire to state that in our opinion very heavy available expenditure is involved in the maintenance of separate medical services for the Navy, Army, and Air Force. The present position is that the Army and Air Force maintain separate medical corps and nursing services. We are informed that the rates of pay granted to Air Force medical officers in 1918 led to increases being made in army rates beyond those originally recommended by the War Office. Apart from the maintenance of separate services, efforts appear to have been made to avoid overlapping by enabling the Air Force to make use of army hospitals and laboratories and to draw medical stores from army supplies. The Naval and Military Medical Services appear to be entirely separate, and we have received remarkable particulars as regards service hospitals at home and abroad which appear to us to indicate very serious duplication. Abroad separate naval and military hospitals are maintained at Bermuda, Hong Kong, Gibraltar, and Malta. The figures of admission to these hospitals given to us for August and September appear to indicate that at each of these stations one hospital would have provided sufficient accommodation.

At home there are twenty-four army hospitals which have another army hospital within ten miles of them. Apart from this the army and navy have separate hospitals each having in some cases more than one) in the following areas:—

Army.	Navy.
Chatham and Gravesend.	Chatham.
Shorncliffe and Dover.	Deal.
Chichester	
Cosham.	Eastleigh.
Gorport.	Porton.
Netley.	Haslar.
Milsey.	
Devonport.	Plymouth.
Pembroke Dock.	Pembroke Dock.
Lisburn.	South Queensferry.

The number of patients in Navy, Army and Air Force hospitals at home on October 21st last, as compared with equipped beds, were as under:—

	Equipped beds.	Patients.
Officers	607	234
Other ranks	11,243	5,101

From which it appears that the hospitals are not half used. A unified medical service would yield substantial benefits, but meantime we consider that the War Office should effect a drastic review of the number of army hospitals with a view to their reduction and concentration, and that arrangements should be made between the War Office and Admiralty similar to those which have already been made between the War Office and the Air Ministry, with a view to the avoidance of duplicated provision, by means of the mutual use of army or navy hospitals, whichever course is more economical in any particular area. We think, also, that disal should be admitted into military and thus effecting a saving in ges."

The Air Force.

The Committee recommend that the Air Force Estimates for 1922-23 should be reduced from £15,500,000 to £10,000,000. This would involve that the Air Units allotted to the navy and army should be lessened by eight and a half squadrons.

The Committee conclude their report on the three fighting services by acknowledging that the suggested reductions would necessarily lead to an increase of the "non-effective" votes. They are of opinion that any such abnormal increase might, in certain circumstances, be regarded as a special charge arising out of the war, and they propose later to put forward their views on this point, and also in regard to such other items as war pensions.

THE SOCIAL SERVICES.

It is remarked that the Provisional Estimates for Government expenditure on social services—namely, education, health, labour, and old age pensions—amounting as they do to £124,000,000, represent nearly four times pre-war expenditure.

Taking into account the sums otherwise raised by the public for the same services—namely, from the rates and by contributions for insurance, the total cost of these social services is stated to have risen from £86,500,000 to £243,500,000 during the period under review. The Committee hold that the development of the Percentage Grant system has materially affected the cost, and suggest that it should be replaced by fixed grants or by grants based upon some definite unit.

Board of Education Estimates.

The Committee make various recommendations to reduce the estimates of the Board of Education for the year 1922-23, from £50,600,000 to £34,500,000, a reduction of £16,100,000, which with the automatic reductions in Scotland would yield £18,000,000. These recommendations include that children should not be taken into State-aided schools until they are 6 years old; that the grants for secondary education and higher education should be restricted; and that teachers should contribute 5 per cent. towards their superannuation pay.

Grants to Universities and Colleges.

Under the above heading the Committee give the following figures:

1913-14. Actual expenditure £181,106 (including £37,463 for non-recurrent grants).
1921-22. Estimate, £2,000,000 (including £500,000 for a non-recurrent grant).
1922-23. Estimate, £1,200,000.

Before 1918-19 annual grants to universities and colleges were provided under many different votes. From that date the expenditure, apart from certain statutory grants to Irish universities, has been collected under a single head. The Treasury now fix the sum to be provided each year, but act on the advice of an independent committee of experts, known as the University Grants Committee, as regards allocation. For the year 1919-20 one million sterling was provided for recurrent grants, and this figure was increased to a million and a half in 1921-22, with an extra half million lump sum non-recurrent to enable universities to improve superannuation provision for their teachers. The Treasury have requested the University Grants Committee to frame their recommendations for 1922-23 so as to bring the expenditure within a total of £1,200,000, being 20 per cent. less than the provision for the current year. The Committee had considered correspondence between the Treasury and the University Grants Committee, in which the latter set out the case for a larger grant. While appreciating the importance of a due measure of State encouragement to universities, which also greatly stimulates local support, the Geddes Committee say that the paramount consideration being national solvency, they recommend that the sum to be provided be £1,200,000, subject to any reduction arising out of Irish changes. They remark that this is two and a half times the pre-war grant.

Ministry of Health Estimates.

The comparative figures given for the Ministry of Health are practically useless because the Ministry was formed in 1919 to take over the duties of the Local Government Board and the work of the National Health Insurance Commission for England and Wales. The Committee acknowledge that strenuous efforts have been made to secure economy and mention that over £3,000,000 has been saved by a restriction of the housing programme and a further £1,000,000 by a reduction in the capitation rate paid the doctors under the Health Insurance scheme. The comparative figures of administration, apart from those of services, are set forth as follows:

	£
1913-14	£181,106
1921-22	£2,000,000
1922-23	£1,200,000

Reduction

The Committee recommend that the Estimates of the Ministry of Health and National Health Insurance for the year 1922-23 should be reduced from £14,233,500 and £350,500 respectively to £22,103,000 in all—this reduction to be apart from any savings on the sale of houses which they advise should be proceeded with vigorously.

Insurance Administration.

The Committee make the following comments on points of detail:

(a) Medical Referee Consultants (£100,000). This provision is in respect of thirty-six whole-time doctors and a number of part-time

doctors who deal with appeals by approved societies against recommendations of panel doctors in cases where there is a dispute as to whether a man's health is such as to require sick benefit. They also supervise medical benefit and do a certain amount of general medical work for the Ministry of Health and other departments. The whole-time doctors are on a five years' engagement as from October, 1920. We understand it is hoped to reduce the sum of £100,000 provided under this subhead to £85,000 gross, and to recover from societies £7,500 by way of fees. It appears that the referees are to some extent a luxury. The societies might revert to the old plan of employing their own referees, which would be less expensive to the taxpayer. If this were done the position of these doctors should be examined with a view to ascertaining what it would cost to terminate their engagements and, in the alternative, whether it would be possible to transfer them to any other Government Department which requires whole-time medical staff—for example, the Ministry of Pensions, which has a large temporary staff.

(b) *Index Clearance Branch (£30,000).*—The position of this branch, instituted in order to meet an objection on the part of medical practitioners to the manner in which the funds available for medical benefit were distributed among individual practitioners, is under consideration by the Minister with a view to its abolition if possible. Unless very strong reason can be shown for the continuance of this branch at public expense we suggest that it should be discontinued. Such an arrangement is not now found necessary in Scotland.

(c) *Public Health Services (£198,000).*—This staff includes the doctors who inspect the various health institutions and whose services are required largely as a result of the State's percentage grant to the local authorities. If our suggestions in the preamble to this part of the Report for replacing percentage grants by some simpler arrangement are adopted considerable reductions in staff should be possible here.

(d) *Welsh Board of Health (Cardiff) (£80,000).*—A board of health was set up in Wales, to which some of the Ministry's functions in Wales were delegated. This has led to unnecessary duplication of staff, and we are informed that £40,000 could be saved if the work were transferred to the Ministry in London, and we suggest that this change should be adopted.

Public Health Services.

The Committee give the following table, showing the growth of expenditure under this heading:

	Tuber- culosis.	Maternity and Child Welfare.	Vener- eal Diseases.	Welfare of the Blind.	Port Sanita- tion.	Total.
	£	£	£	£	£	£
1913-14	117,000	—	—	—	—	117,000
1914-15	172,000	11,000	—	—	—	183,000
1915-16	245,000	41,000	—	—	—	286,000
1916-17	236,000	68,000	—	—	—	304,000
1917-18	361,000	122,000	84,000	—	—	567,000
1918-19	508,000	219,000	144,000	—	—	871,000
1919-20	548,000	512,000	224,000	23,000*	—	1,307,000
1920-21	754,000	800,000	103,000	109,000	67,000	2,033,000
1921-22†	1,002,000‡	1,012,000	404,000	101,000	67,000	2,815,000
1922-23	1,429,000‡	1,162,000	421,000	85,000	50,000	3,210,000

* Part year only.

† Exclusive of non-recurrent expenditure totalling £220,000.

‡ In addition to capital grants of £45,000 in 1921-22 and £350,000 proposed for 1922-23.

It is remarked that with the exception of the grant for the Welfare of the Blind, all these grants have increased in an extremely rapid increase of the grants in their opinion, the danger attaching to the grants they hold, be replaced by a system of block grants. The Ministry of Health, they state, concur that from an administrative point of view it would be a great saving to get rid of the grants on a percentage basis, but that there is practical difficulty in doing so. The Committee suggest that if no more grants on a percentage basis for measuring grant can be reached, the Government should adopt the basis of previous expenditure, at any rate while the present financial stringency continues. The Committee proceed to make the following recommendation:

	Ministry's Proposal.	Committee's Recommendation.
Tuberculosis (maintenance) ...	£1,489,000	£1,202,000
Tuberculosis (capital) ...	360,000	352,000
Maternity and Child Welfare ...	1,162,000	1,012,000
Venerable Diseases ...	421,000	424,000
Welfare of the Blind ...	85,000	85,000
Port Sanitation ...	50,000	NIL.
	£3,570,000	£3,113,000

The reason for proposing that the Port Sanitation grant should be dropped is that until recently it was entirely borne by the locality. With regard to the other items, the Committee submit that the amounts allocated will not, with falling prices and scrupulous economy, reduce the amount of undeniably valuable work being done. They hold that the grants to local authorities should be given contingently upon there being no reduction in treatment, that they should be subject to review, and they should not be on a percentage basis.

Increase of Insurance Contributions.—The Committee give the comparative figures for insurance as follows:

Expenditure—	£
1913-14	3,501,255
Estimate—	
1921-22	8,842,550
1922-23	7,802,000

In reviewing the position of National Insurance, the Committee state that they have been greatly impressed by the fact that very many and costly alterations have been made in the original scheme on which the 1911 Act was based, and that in the main the taxpayer has shouldered the burden. They refer to these matters sectionally:

1. The increase in the cost of medical benefits.
2. The increase of sickness claims of women over the original actuarial estimate, this increase involving a grant in aid of £350,000 a year.
3. The extra provision of £150,000 a year between 1917 and 1921 to the Central Fund.
4. The share by the State in the increase of contributions, together with its acceptance of responsibility for a charge of £351,000 per annum in respect of the old sanatorium benefit.
5. The cost of medical referee consultants and of the index clearance scheme.

The Committee hold that a revision of health insurance finance will be necessary, and that then the points mentioned above will have to be considered. The estimated Exchequer cost of national insurance for Great Britain in the current financial year (included in the total estimates for the Ministry of Health) is £10,500,000. The provisional estimate for 1922-23 is about £9,200,000. This reduction has been largely brought about by a reduction of 1s. 6d. (11s. to 9s. 6d.) in the doctor's capitation fee, as already noted. The Committee consider it is essential that the State's share in the insurance burden should be further diminished. They recommend that the contributions by employers and employed should therefore be increased by a halfpenny a week in each case, the change to be introduced on July 1st. This would admit of the abolition of the Exchequer grant for medical services, and as the increase in contributions is suggested in order to relieve the taxpayer, the Committee advise that these extra contributions should not carry any State grant, which normally is in the proportion of two-ninths.

Employment Exchanges and Unemployment Insurance.—The Committee recommend that the abolition of the employment exchanges and of the Ministry of Labour should be considered, except in so far as the employment exchanges are required for checking payments of unemployment benefits. They advise that a committee of experts should be set up with a view to simplifying the unemployment insurance scheme, amalgamating unemployment and health insurance cards, records, and, as far as possible, administration.

Ministry of Pensions Estimates.

The comparative figures of the estimates of the Ministry of Pensions are given as follows:—

	£
1921-22 net estimate ...	111,556,656
1922-23 net estimate ...	56,351,000
Reduction ...	15,191,656 (or 13.6%)

The Committee state that the greater part of this reduction is due to an over-estimate for the year 1921-22, amounting to £10,500,000. The gross estimate for 1922-23 is analysed as follows:—

	£
Pensions (excluding parents' pensions) ...	67,171,000
Treatment ...	13,455,000
Parents' pensions ...	9,230,000
Special Grants Committee and miscellaneous items ...	789,000
Administration ...	5,722,000
	9,355,000

The Committee report they cannot suggest a reduction in the provision of £57,170,000 for ordinary pensions until the time fixed for review in April, 1923, when revision will take place on the basis of the ascertained cost of living. They think that the cost of treatment, parents' pensions and administration, can be reduced without inflicting any undue hardship. They recommend, therefore, that the estimate be brought down from £96,366,000 to £93,030,000, a reduction of three and one-third millions.

Dealing with treatment, the Committee recall that a disabled man is entitled to free medical attention when it is certified that he needs it, and if he is deemed unable in consequence to provide for his own support and that of his family, he receives treatment allowance in addition to his pension. It is estimated that in 1922-23—

The cost to the Ministry of providing treatment will be ...	£ 6,919,000
And the treatment allowances paid will amount to ...	6,536,000

Making a total estimated expenditure of ... 13,455,000

The number of men under treatment increased between June 30th, 1920, and June 30th, 1921. Over 500,000 individual spells of treatment are given annually, the average length of the spell being sixteen weeks. The Ministry of Pensions are of opinion that the numbers under treatment reached a maximum about June, 1921, and may be expected to decline. The explanations of

the increase between June, 1920, and June, 1921, are (a) that there has been a waiting list of men seeking treatment, and (b) the scarcity of employment during the last fifteen months.

The methods by which the Committee think that economies are attainable can be briefly summed up.

They find that the accommodation at Ministry hospitals is rather under 14,000 beds, and that the number unoccupied was 2,450. They advise that more rapid progress should be made in reducing this accommodation. There are 11,656 beds in Admiralty and War Office hospitals in this country, and of these 5,335 are filled and 6,571 are unoccupied. Thus in the three departments the taxpayer is providing 25,556 beds, and of that number 9,821 are unoccupied. Immediate steps should be taken to utilize the spare accommodation in naval and military hospitals, thus enabling buildings hired by the Ministry of Pensions to be surrendered. The Committee are not satisfied that the fullest possible use is being made of civil hospitals. It appears that, including cost of accommodation, each patient in a Ministry of Pensions hospital is estimated on the average 10s. 11d. a day, whereas the capitation rate of civil hospitals averages 9s. a day. The Committee notes that the Minister proposes to make various reforms in the matter of treatment as and when pensions are made permanent. They suggest that the question of introducing these reforms earlier should be considered, and in particular a strict limitation of home treatment, and it is admittedly unsatisfactory and leads to abuse. Treatment allowances become even more generous when a man is entitled to health insurance benefits, rank allowance, or service pension. In hospital a man receives 40s. a week the equivalent of (full disability allowance) in addition to allowances in respect of his wife and children, and out of this he contributes only 19s. a week towards his maintenance in hospital. The cost of the maintenance averages from 65s. to 76s. 5d. a week.

The Committee further point out that the number of orderlies employed in Ministry hospitals is equivalent to one for six patients, and they submit that patients who are in a condition to do so should do more light work.

The suggested savings would work out as follows per annum:

Allowances reduced by the amounts received for	£
... ..	1,000,000
... ..	500,000
... ..	416,000
... ..	250,000

Having regard to the above suggestions and the further economies which would result from reducing the number of orderlies and making fuller use of naval, military, and civil hospitals, the Committee consider that the sum provided for treatment in 1922-23 might be reduced from £13,455,000 to £11,000,000.

The estimated cost of administration for 1922-23, excluding £1,400,000 for the staffs of hospitals and institutions, which has been included above as part of the cost of "treatment," is made up as follows:

	Salaries and Wages	Travelling and Incidental Expenses
Headquarters and regional staffs	£2,650,000	£81,000
Medical staffs	1,777,000	40,000
Local committee staffs	934,000	200,000
	£5,461,000	£221,000

The Committee suggest that the pay of the temporary administrative medical staff of the department, numbering 324, whose average is £972 per annum, requires reconsideration in view of the fall of the cost of living and the reduction recently effected in the emoluments of panel doctors.

Board of Control.

It is recommended that the necessary steps be taken to change this grant from a percentage basis to a *per capita* basis. This applies to England, Wales, and Scotland.

LEICESTER PUBLIC MEDICAL SERVICE.

THE report of the Board of Management of the Leicester Public Medical Service for the year 1921 records the continued success of the work. The Board decided that members of the medical profession who have rendered conspicuous service to the Service shall be eligible to be appointed honorary life members, and that Dr. A. Higgs and Dr. J. E. White be so appointed.

The subscribers to the various sections of the Service numbered nearly 40,000, and besides these about 12,000 State insured members of the Friendly Societies are paid for through the Service. The Board has continued the arrangement whereby free medical treatment is provided for the uninsured blind of Leicester, under the care of the Institution for the Welfare of the Blind, the members of the Cripples' Guild, and the Wycliffe Society for Helping the Blind. The number of prescriptions dispensed during 1921 was 185,260; in the previous year it was 185,790.

The arrangement with the Education Committee for accommodation to be provided at the central dispensary for the dental work of the school clinic has been continued. A consulting room at the central dispensary, with waiting room accommodation, has, by arrangement with the Ministry of Health, been provided for the purposes of the Regional Medical Officer; and the Board has again entered into an arrangement with the Leicester Guardians for the dispensing of the necessary medicines for the outdoor sick poor.

The committee of the Leicester Subdivision of the Union of Medical Practitioners, in presenting its report for 1921, states that the scheme for collective locumtenencies during sickness or short absences "was in operation from October 1st, 1920, to March 31st, 1921, and proved very useful. The scheme of collective locumtenencies for the summer holidays inaugurated during 1919 was successfully continued during the period from April 1st to September 30th, 1921. Eighteen doctors took advantage of the scheme.

At a special general meeting in July, it was unanimously resolved that a levy of one farthing per annum, per insured person, on the list of panel practitioners be made, and that of the proceeds £50 be subscribed to the Royal Medical Benevolent Fund and the remainder to such other medical or allied charities as the committee might direct. The levy yielded £107 14s. 4d.

The honorary secretary of both organizations is Dr. W. Moffat Holmes.

INSURANCE ADMINISTRATION.

THE Minister of Health and the Minister of Labour have jointly appointed an inter-departmental committee to consider the relations of health insurance and unemployment insurance, and to investigate the possibility of reducing the total cost of administration by modifying the unemployment insurance scheme, and by amalgamating unemployment and health insurance cards, records, and, as far as possible, administration.

The committee consists of

Sir Alfred W. Watson, Government Actuary (chairman).
Sir W. S. Knibb.
Mr. E. J. Strohmeier.
Mr. S. P. Vivian (Ministry of Health).
Mr. James Leishman (Scottish Board of Health).
Sir David Shackleton.
Mr. T. W. Phillips.
Mr. F. G. Bowers.
Mr. J. F. G. Price (Ministry of Labour).
Mr. F. Phillips (Treasurer).
Mr. A. Henry (Actuary's Department).
The joint secretaries are Mr. J. M. Glen, of the Ministry of Labour, and Mr. A. W. Neville, of the Ministry of Health.

Naval and Military Appointments.

ROYAL NAVAL MEDICAL SERVICE.

THE following appointments are announced by the Admiralty.—Surgeon-Commander R. F. Clark to the *Colony* as Health Officer and District Commander-in-Chief, east of Scotland, and a Medical Transport Officer, Broadway, lent to R.M.A. Eastons, Surgeon Lieutenant-Commander E. Cameron to the *Fleet* for R.N. Barracks, Portsmouth; Surgeon Lieutenants: A. R. McKillop to the *Marborough*, G. Aubrey to the *Star*, and for duty in the *Centurion*.

ARMY MEDICAL SERVICE.

ROYAL ARMY MEDICAL CORPS.

Lieut.-Colonel J. C. Kennedy to be temporary Colonel whilst specially employed.

Major J. W. Houston, D.S.O., to be temporary Lieutenant-Colonel whilst employed as Assistant Director of Pathology.

Captain O. W. J. Wynne to be temporary Major from February 27th to October 5th, 1920.

The following Captains relinquish the acting rank of Major: Private Major A. G. J. MacLennan, C.I.E., R. McKim, J. M. Macle, M.C.

The following Captains to be acting Majors: K. L. O'Sullivan from October 29th to November 21st, 1921; H. E. P. York, M.C., from December 6th, 1921, to June 6th, 1922; D. W. John, M.C., from November 15th, 1920, to January 15th, 1921.

Captain J. E. Hepper is restored to the establishment.

Lieutenant (temporary Captain) J. C. Coates to be Captain.

Temporary Captain R. W. Mudd relinquishes his commission and retains the rank of Captain.

TERRITORIAL ARMY.

ROYAL ARMY MEDICAL CORPS.

The following vacate the appointment of Honorary Colonel of the Division shown against their names: Honorary Colonel (Honorary General) ret. Major Sir A. Keogh, G.C.B., G.C.V.O., C.B., and Lorden Division.

Honorary Colonel T. R. Gibson, West Lancashire Division.

Honorary Colonel T. F. Reside, B. R. R. C. B. V.D., West Riding Division.

Honorary Colonel Sir J. Williams, Bt., G.C.V.O., West Anglian Division.

Colonel Sir T. Clifford, R.C.B., F.R.S., East Anglian Division.

The following officers to be Honorary Colonels of the Division shown against their names: Honorary Major-General Sir R. G. A. Northam, R.C.M.G., C.B. (from T.A. Res.), West Riding Division. Honorary Major-General Sir R. G. A. Northam, R.C.M.G., C.B. (from T.A. Res.), West Riding Division.

General Sir A. A. Bowlby, K.C.B., K.C.M.G., K.C.V.O. (ret.), South Midland Division. Colonel J. A. Jones, V.D., K.H.S. (ret.), Welsh Division. Colonel J. Griffiths, C.M.G., T.D. (from 1st Eastern General Hospital) East Anglian Division. Colonel J. V. W. Rutherford, V.D. (from T.A. Res.), Northern Division. Lieut.-Colonel A. Thorne, V.D. (ret.), 2nd London Division. Lieut.-Colonel F. J. Knowles, T.D., West Lancashire Division. Lieut.-Colonel Sir W. R. Smith, T.D. (from Sanitary Service), Home Counties Division.

Major D. Mackie, M.C., late R.A.M.C., S.R., to be Captain, with precedence as from April 1st, 1915, and to relinquish the rank of Captain.

The following officers having attained the age limit are retired, and retain their rank except where otherwise stated: Lieut.-Colonels T. F. Dewar, T.D., J. Mill, V.D., and T. H. Openshaw, C.B., C.M.G., and are granted the rank of Colonel with permission to wear the prescribed uniform. Lieut.-Colonel C. E. Douglas, V.D., T.D., with permission to wear the prescribed uniform. Majors A. C. Turner, D.S.O., T.D., J. B. Stevens, T.D., H. Kelly, T.D., J. W. Cook, T.D., and C. Vise, T.D., with permission to wear the prescribed uniform. Captain W. T. Ritchie, O.B.E., and is granted the rank of Major. Captains W. H. Buckley, H. Smith, A. B. Winder, B. G. Ewing, G. B. Pearson, J. H. Churchill, W. H. H. Bennett. Captain F. M. Halley is seconded under par. 112, T.A. Regulations, April 1st, 1920.

The following officers relinquish their commissions and retain their rank, except where otherwise stated: Lieut.-Colonels H. C. Donald, T.D., and J. R. Harper, C.B.E., T.D. (with permission to wear the prescribed uniform); Majors A. Innes, J. Walker, G. Potts; Captains (Brevet Majors) W. R. Bristow (and is granted the rank of Major), H. Sharpe; Captains G. H. H. Mansfield, H. Paterson, J. F. Edmiston, B. Hughes, D.S.O., J. H. Crane, M.B.E., H. Drummond, R. E. T. Tatlow (and are granted the rank of Major); J. Fraser, H. F. L. Hngo, M.C., A. Hamilton, A. C. Ainsley, M.C., J. A. Thomson, A. C. Haddow, L. W. Sparrow, G. Crawshaw, M.C., F. C. Nichols, M.C., A. N. Worsley, L. S. Willox, C. Mcarns.

Captain W. R. Collingridge resigns his commission and retains the rank of Captain.

Captain P. D. Warburton (R. of O.) to be Captain with precedence as from March 20th, 1915.

SANITARY SERVICE.

Major (Brevet Lieut.-Colonel) H. F. Horne, T.D., relinquishes his commission, and retains his rank, with permission to wear the prescribed uniform.

Captain A. Davidson (late R.A.M.C.) to be Captain, with precedence as from November 4th, 1919.

DIARY OF SOCIETIES AND LECTURES.

LONDON DERMATOLOGICAL SOCIETY, 49, Leicester Square, W.C.—Tues., 4.30 p.m., Pathological Specimens and Cases. 5.15 p.m., Dr. Knyvett Gordon: Clinical Significance of Histological Examination of the Blood.

MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.—Mon., 9 p.m., Third Letician Lecture by Sir Leonard Rogers, C.I.E., M.D., F.R.S.: Amoebic Liver Abscess: its Pathology, Prevention, and Cure.

ROYAL SOCIETY OF MEDICINE.—Special General Meeting of Fellows, Tues., 5 p.m. To be followed immediately by a General Meeting for election to Fellowship. Section of Pathology: Tues., 8.30 p.m., Dr. M. H. Gordon: Recent Studies of Streptococci. Dr. J. W. Trevan: Apparatus for Measuring Very Small Quantities of Fluid. Dr. J. C. Mottram, Dr. W. Cramer, and Dr. A. H. Drew: Demonstration of Effects of Exposure to Radium and of Withholding of Vitamins on Fat Absorption. Dr. E. H. Kettle: Demonstration of Pathological Specimens. Section of Bacteriology and Climatology: Thurs., 4.30 p.m., Discussion on the Etiology of Gout to be opened by Dr. R. L. Jones Llewellyn. The members and guests will dine together at 7 p.m. Those intending to be present should notify Dr. C. F. Sonntag, 80A, Belsize Park Gardens, N.W.3, by February 21st. A Clinical Meeting of the Section will be held on Fri., February 24th, at a London Hospital to be announced. Section of Urology: Thurs., 8.30 p.m., Professor P. J. Cammidge: Source of the Amyolytic Ferment of the Urine. Dr. G. A. Harrison: Glycosuria in Renal Disorders. Section of the Study of Disease in Children: Fri., 4.30 p.m., Cases. 5 p.m., Dr. C. R. Lapage and Dr. W. J. S. Rythell: Tonic and Atonic Hearts in Children. Section of Epidemiology and State Medicine: Fri., 8 p.m., Dr. Evelyn D. Brown: Relation between Puerperal Septicæmia and other Infectious Diseases, with Reference to Admission of Maternity Cases into Isolation Hospitals.

POST-GRADUATE COURSES AND LECTURES.

CANCER HOSPITAL, Fulham Road, S.W.—Tues., 4 p.m., Sir Charles Ryall: Cancer of the Tongue. Fri., 4 p.m., Mr. W. E. Miles: Cancer of the Rectum.

CHESTERFIELD DIVISION, BRITISH MEDICAL ASSOCIATION, Chesterfield Royal Hospital.—Fri., 2.30-4 p.m., Professor Melanby: Diet and Disease; Dr. King: Climatærie Haemorrhages.

EDINBURGH ROYAL HOSPITAL FOR SICK CHILDREN.—Thurs., 5 p.m., Miss Gertrude Hezleld: Orthopaedics in Infancy.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION, Royal Maternity and Women's Hospital.—Wed., 4.15 p.m., Dr. S. J. Cameron: Obstetrical Cases.

HOSPITAL FOR SICK CHILDREN, Great Ormond Street, W.C.—Thurs., 4 p.m., Mr. Pitts: Dental Aspects of Cleft Palate.

MANCHESTER BABIES' HOSPITAL, St. Anne Lane, Levenshulme.—Sat., 4 p.m., Dr. Catherine Chisholm: Acute Dyspepsia.

MANCHESTER ROYAL INFIRMARY.—Tues., 4.30 p.m., Dr. E. M. Brockbank: Angina Pectoris.

MANCHESTER: ST. MARY'S HOSPITALS (Whitworth Street West Branch).—Fri., 4.30 p.m., Dr. Lacey: Leucorrhœa.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westminster Street, W.—Daily, In- and Out-patient Attendances. Mon., 5.30 p.m., Lecture by Dr. Hamill: Aneurysm.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen Square, W.C.—Mon., Tues., Thurs., and Fri., 2 p.m., Out-patient Clinics. Tues. and Fri., 9 a.m., Surgical Operations. Lectures.—Mon., 12 noon, Dr. Greenfield: Poliomyelitis and Encephalitis Letargica. 3.30 p.m., Dr. Adie: Combined Degeneration in the Spinal Cord. Tues., 3.30 p.m., Dr. James Taylor: Ocular and Visual Disturbances in Diseases of the Nervous System. Wed., 3.30 p.m., Mr. L. Paton: Optic Atrophy. Thurs. and Fri., 3.30 p.m., Dr. G. Stewart: Tumours of the Spinal Cord.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.15.—Daily, 2.30 p.m., In- and Out-patient Clinics, Operations, etc. Lectures.—Mon., 3.30 p.m., Dr. L.

Yealand: Examination of the Nervous System—Sensory. Tues., 2.30 p.m., Dr. J. Metcalfe: X-ray Treatment. Thurs., 4.30 p.m., Mr. H. W. Carson: Intestinal Obstruction.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell Square, W.C.—Wed., 4 p.m., Dr. P. C. Varrier Jones: Industrial Colonies and Village Settlements for the Consumptive.

ST. JOHN'S HOSPITAL, 49, Leicester Square, W.C.—Thurs., 6 p.m., Chesterfield Lecture by Dr. W. Griffith: Bullous Eruptions.

ST. MARLBORNE GENERAL DISPENSARY, Welbeck Street, W.—Dr. E. Pritchard: 6 p.m., Wed., Modification of Milk; Fri., Uses of Dried Milk and Patent Foods.

SALFORD ROYAL HOSPITAL.—Thurs., 4.30 p.m., Mr. Smalley: Indications for Operation in Stipulative Diseases of the Middle Ear.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Municipal Hospital, Ouseley Road, Balham.—Wed., 4 p.m., Dr. C. Lakin: A Clinical Demonstration.

WEST LONDON POST-GRADUATE COLLEGE, Hammersmith, W.—Daily, 10 a.m., Ward Visits; 2 p.m., In- and Out-patient Clinics and Operations. Lectures.—5 p.m., Mon., Mr. B. Harman: Squint. Tues., Dr. Pritchard: Intravenous Forms of Treatment. Wed., Mr. D. Armour: Practical Surgery. Thurs., Professor E. H. Starling: Compensation and its Failure in Heart Disease. Fri., Dr. G. Stewart: Nervous Diseases.

British Medical Association.

OFFICES AND LIBRARY, 429, STRAND, LONDON, W.C.2.

Reference and Lending Library.

THE READING ROOM, in which books of reference, periodicals, and standard works can be consulted, is open to members from 10 a.m. to 6.30 p.m., Saturdays 10 to 2.

LENDING LIBRARY: Members are entitled to borrow books, including current medical works; they will be forwarded, if desired, on application to the Librarian, accompanied by 1s. for each volume for postage and packing.

APPOINTMENTS.

MACARTHUR, John, M.R.C.S., L.R.C.P., Medical Superintendent, Fracebridge Mental Hospital, Lincoln.

TREVES, F. B., O.B.E., M.B., Medical Referee under the Workmen's Compensation Act, 1906, for County Court Circuit No. 49, and to be attached more particularly to the Margate and Ramsgate County Courts.

HOSPITAL FOR DISEASES OF THE THROAT, Golden Square, W.—Honorary Assistant Surgeons: Bedford Russell, F.R.C.S., and F. C. Ormerod, M.D., F.R.C.S. Edin.

BIRTHS, MARRIAGES, AND DEATHS.

The charge for inserting announcements of Births, Marriages, and Deaths is 9s., which sum should be forwarded with the notice not later than the first post on Tuesday morning, in order to ensure insertion in the current issue.

BIRTHS.

ALLEN.—On February 12th, at 111, Mount Pleasant, Liverpool, to Dr. and Mrs. W. T. D. Allen, a son.

GOODWIN.—On February 9th, at Conyers House, Newcastle-upon-Tyne, the wife of Cecil G. R. Goodwin, L.R.C.P., of a daughter.

WATERHOUSE.—On February 7th, at 25, The Circus, Bath, Mabel, the wife of Dr. Rupert Waterhouse, M.R.C.P., of a son.

DEATH.

WEBSTER.—On Sunday, January 29th, at Heathfield, Sussex, William Frederick Webster, M.R.C.S., L.R.C.P., aged 61.

of several years, during which there was exasperation on the part of Insurance Committees and doctors who found themselves credited with a smaller portion of the Central Pool than their inflated lists seemed to justify, the Index Clearing Branch was set up, and has done good service. It has reduced the inflation considerably, but has not nearly finished its work, and if it is dropped much of the inflation that has been cleared up will return. The Branch may not be absolutely indispensable, but its loss will be a doubtful economy, as the old complaints will be bound to recur, and no business man could be in favour of the exceedingly inaccurate lists which have formed the basis of the grants from the Central Pool to the insurance areas. In fact, if it were not for a belief that the inflation was pretty generally and equally distributed the position would have been intolerable.

The paragraphs of the report dealing with the medical side of the Ministry of Pensions are inconclusive. At present the Ministry has 14,000 beds, which is much less than the demand originally made. The number of beds occupied on June 30th, 1921, was 11,600, but the Committee thinks that though the accommodation is being steadily decreased more rapid progress in this direction is desirable. It reverts to its proposals to make use of the naval and military hospitals, and suggests that the fullest possible use is not being made of civil hospitals.

In the SUPPLEMENT for this week will be found a detailed analysis of the report, which contains an immense amount of information with regard to national expenditure not easily to be obtained elsewhere.

CAESAREAN SECTION.

It is satisfactory to find that the *Journal of Obstetrics and Gynaecology of the British Empire*, which passed into a state of suspended animation during the war, has been resuscitated. That its second lease of life promises to be at least as vigorous as its first is evidenced by the fine double number recently published, and we are glad to take this opportunity of congratulating the editors. Practically the whole of this double number is devoted to the subject of Caesarean section, and the collected papers and reports form a highly valuable contribution to the obstetric literature of the period. The papers which were read by Professor Munro Kerr and Mr. Eardley Holland at the Newcastle meeting of the British Medical Association are reprinted here in full from our columns; and as the editorial staff of the *BRITISH MEDICAL JOURNAL* gave the editors of the sister journal special facilities, we may well feel that we have some little share in the success of this new number of the latter.

No subject in obstetrics or gynaecology is being more written about and discussed at present than Caesarean section. This is partly a direct outcome of the "boom" in popularity from which, we think we may quite legitimately say, the operation is "suffering." In part it is a manifestation of the beginning of a reaction against certain excessive tendencies which have been showing themselves. The psychology of the collective mind of the profession is too complicated for us to try to determine precisely why this rush of popularity should have occurred exactly now. Doubtless the publication of Amand Routh's collective statistics in 1911 drew widespread attention to the amazing character of the progressive improvement in the prognosis for both mother and infant that was being achieved in connexion with the operation; and since then the widening of the relative indications for the operation has assuredly added vastly to the interest surrounding the subject. No longer is it a desperate remedy in certain cases of contracted pelvis or of labour obstructed by tumours;

Professor Munro Kerr discussed mere or less fully a round dozen of indications at Newcastle, ranging from those mentioned above, through eclampsia and *ante-partum* haemorrhage, to prolapse of the cord. The indications were derived from an analysis of 4,197 cases between the years 1911 and 1920 inclusive. This analysis has been very carefully and profitably carried out by Mr. Eardley Holland and the statistical data are of the greatest value, providing as they do a means of studying the place which the operation holds at the moment in this country.

The double number we are considering affords the reader an almost complete survey of the present position. Indeed, it is, in many respects, like reading the report of a full-dress debate on the subject. In Mr. Eardley Holland's collective statistics, and in the numerous reports of individual cases by different operators, we have a large mass of valuable material provided for discussion. Again, we have the argument in favour of the progressive widening of the indications for Caesarean section ably stated by Professor Munro Kerr, while the negative is equally ably argued by Dr. Blacker. We would not be misunderstood in expressing matters thus, because while Professor Munro Kerr is avowedly anxious to see the technique of the operation so improved, and the mortality so diminished, that the indications for the operation may indeed be widened, he is, at the same time, clearly cognizant of its limitations. Similarly, Dr. Blacker, while making a very urgent plea for the better recognition of these limitations, is very wide awake to the unrivalled value of the operation within certain limits. The burden of Dr. Blacker's argument is what we believe all obstetricians of mature judgement have been feeling for some time—namely, that the very ease and safety of Caesarean section under modern conditions is leading to its abuse. It is an easier operation to perform than almost any other operative method of delivery save low forceps; it is rapid; and, lastly, it is showy. Hence the danger of its coming to be regarded as a sort of panacea for all obstetric ills. That this tendency is not confined to this country is obvious from the best American literature on the subject. In his recent monograph on Caesarean section Dr. Franklin Newell, Professor of Clinical Obstetrics at Harvard, writes: "The increased success which has attended the performance of Caesarean section as an operation of election instead of as an operation of last resort has led to its employment in many cases, to the exclusion of methods of delivery better suited to the needs of the given patient, until at the present time it is the most abused obstetric operation, being performed by comparatively untrained surgeons on patients who present no real indication for it, under conditions which render it an exceedingly dangerous procedure. It is not at all unusual at the present time to see patients who have been subjected to Caesarean section for no apparent reason, as far as physical examination shows, and the only logical conclusion seems to be that the operative indication has been a slow, though normal, labour, which the attendant has hastened to end in the manner easiest for himself though often not best for the patient. The increasing safety of abdominal surgery, combined with the fact that the operation is much easier to perform than any but the easiest of tetra operation, has caused a loss of perspective and to-day there is no question but that Caesarean section is one of the most abused operations in surgery. . . . I am convinced that Caesarean section as performed by local operators in small communities for the indications furnished by the local practitioner of obstetrics is one of the most fatal of surgical operations."

This is a sweeping indictment, and we are glad to think that it is probably not, or at least not so widely,

applicable to conditions of practice in this country; but that the temptation to perform an easy, quick, and dramatic operation, instead of following the safer and better, but more difficult and more tedious path of ordinary obstetric methods, is being yielded to by men in this country, and amongst them "experts," is evident to anyone who cares to read this double number. Uterine inertia, abdominal pain, epilepsy, hydramnios, hydrocephalus, varicose veins, neglected transverse presentations!—the mere mention of these conditions as indications for Caesarean section is enough to show that the operation is indeed being abused here and now, and that there has already developed that lack of perspective to which Professor Newell refers. It suggests, to quote the words of an eminent and experienced obstetrician in this country, that "the art and science of midwifery have either been lost by the younger generation in this country or will certainly be lost if this mad rage for Caesarean section is continued." The next quinquennium, before another collective analysis of statistics is made, might very profitably be devoted rather to consolidating the ground already won than to trying to gain more ground—to an endeavour to demarcate clearly the precise limitations of the operation in connexion with the various indications rather than to widening these indications.

This is not the place to discuss seriatim the points at issue between Dr. Blacker and those who are pursuing the "mad rage" for Caesarean section, but his main contention stands unchallenged—namely, that up to the present in connexion with a number of possible indications the Caesarean operation does not show an improved mortality as compared with the older and more tried methods of treatment. In many cases Caesarean section affords a better outlook for the child, and this is all to the good; but we must never lose our sense of the proportionate value of maternal life as compared with foetal life, and only in the most exceptional circumstances is it justifiable to expose the mother to an increased risk in the interests of the unborn child.

One of the most important points brought out in Mr. Holland's statistics, and in a paper which he read before the Royal Society of Medicine and now reproduces, is the very real nature of the risk of rupture of a Caesarean section scar during a subsequent pregnancy or labour. Mr. Holland's investigations lead him to put this as a 4 per cent. risk, and that is a figure which calls for very serious consideration. Some individual operators can, of course, show a clean sheet so far as this risk is concerned, but their records are of less value than a collective record such as Mr. Holland has made, where the individual element can be excluded. After all, wisdom and asepsis do not dwell exclusively with individual operators, and the personal element in a one-man series is apt to be misleading to all others except the individual operator himself. We know of one great hospital in this country where 4 cases of ruptured Caesarean scars have been seen since the collection of Mr. Holland's statistics. Many women have been operated upon repeatedly by Caesarean section, some as often as six or seven times without disaster, but that only serves to emphasize the truth of the general statement—"Once a Caesarean, always a Caesarean." This, again, is a point of the utmost weight in considering the place of the operation in regard to such relative indications as placenta praevia, eclampsia, and so forth.

The main causes of rupture of the Caesarean scar appear to be infection of the uterine wound during healing, imperfect methods of suture, and improper suture material. Professor Munro Kerr has some hope that the use of the lower segment incision will abolish, or greatly diminish, this risk. Certainly, that area presents anatomical and physiological features which, theoretically at least, should make for better healing than the upper

segment. So far only one case of rupture of an old Caesarean scar in this site has been reported. The operation is rather more difficult to perform than the classical method, and in only a very limited number of cases has the operation been done by this route in this country. It is too soon, therefore, to draw any conclusions as to the safety of this method of operating from the point of view of subsequent rupture.

In regard to the question of indications, there appears to be a general consensus of opinion against eclampsia as being a good indication. Emphasis is being more and more placed where it ought to lie—namely, on the importance of prophylaxis. It rests with the women of this country, as well as with the medical profession, to make eclampsia all but an extinct disease. It is wholly a matter of education as to simple routine measures, but where eclampsia has occurred the pendulum seems to be swinging in favour of non-interference, and this must be regarded as a particularly interesting phenomenon when we bear in mind both the modern placental theories as to its etiology and this modern enthusiasm for Caesarean section. Placenta praevia provides grounds for more divergence of opinion. There is an apparent disregard of the child's chances in the employment of internal version—more apparent than real, it is true, when regard is had to the probable prematurity of the child and the risks of its death from placental separation. From the point of view of the child, Caesarean section is incomparably the best method of treating a placenta praevia, but where there is any balance between the child's life and its mother's, opinion in this country will never hesitate to favour the mother. In this connexion Dr. Blacker's paper calls for careful study. We are in complete agreement with him that Caesarean section must not only hold out a better chance for the child, but it must offer at least an equally good chance for the mother before it can claim superiority over old and tried methods of treatment.

EPIDEMIOLOGICAL INTELLIGENCE WORK.

WHEN the mortality, or prevalence, of an epidemic disease has passed definitely above the endemic level, but before the whole extent of its ravages has been made manifest, it is natural to attempt some forecast of its effects. The question may therefore be put, whether in the present state of knowledge any forecasts better than mere guesses can be made in the case of influenza. As we have had occasion recently to recall, Dr. Farr attempted more than once to place epidemiological forecasting on a sound theoretical basis. Farr used two methods, each of which postulated a certain functional relation between the logarithms of the numbers of cases, or deaths, recorded in successive intervals of time. The first of these methods (that alluded to in the article published on January 28th) imposed a symmetry upon the evolution of an epidemic, and, as Dr. Brownlee has pointed out, must be regarded as at least a first approximation to the "law" of various epidemic diseases. The second method, used by Farr in the case of the cattle plague of 1866, did not involve a symmetrical evolution but led to a curve for which a biological foundation would be hard to find. Merely as instruments of practical forecasting, neither method is of much service in the study of influenza. Thus, to take the case of London, we pointed out that if the four weeks beginning with that ending on December 24th were taken as a basis, Farr's first method would require 678 deaths in the week ending January 21st and 616 in the following week, figures very wide of the truth.* The second method is no more successful. It does, indeed, predict the next figure (that for the week ending January 21st) very closely, requiring 451 deaths, where 443 were actually

* Owing to an arithmetical slip, we gave the "calculated" figures for the weeks used as 54, 238, 342, and 557; these should have been 53, 156, 342, 557; the observed values were 54, 151, 354, 551.

recorded. But it forecasts 154 for the week ending January 25th, when the real figure was 320. The explanation is, of course, that the postulated "laws" are only two of myriads of arithmetical relations which might be tried and that there is no particular reason why they should succeed in this case. The touch of genius in this work of Farr's is not the particular formula but the scientific imagination which recognized that we do have to deal with an orderly phenomenon and may hope to describe it. Since Farr's time we have learnt a good deal about the types of function which describe epidemiological statistics—Professor R. A. Fisher, Sir Ronald Ross, and Dr. John Brownlee have taught us much. But it is still true that to adapt the constructs of any of these investigators to the immediate purposes of the forecaster—that is, to "fit" the curves when only a portion of the frequency is known—is not yet practicable. We have therefore to fall back upon the legal method of searching out a precedent, the course taken by the Ministry of Health in their statement to the press where it was remarked that the current epidemic had affinities with that of the spring of 1895 in London. Let us now see how far this precedent is of service. That epidemic began in February, 1895; in successive weeks from the second week of February the numbers of deaths registered under the heading influenza were 13, 24, 111, 296, 473, 349, 225, 116, 63, 46. Returning now to our basis of 54, 151, 354, 551, is there any affinity between the two cases in the matter of rate of increase? We note at once that 111 bears nearly the same proportion to 296 that 54 bears to 151, and a somewhat higher proportion than 151 to 354, while 296 is in almost the same proportion to 473 as 354 to 551—namely, as 1 to 1.6. A first suggestion, then, is to multiply all the weekly totals of the 1895 epidemic by the ratio of 551 to 473, and to take these products as the prediction. This will give us, comparing the "calculated" with the known figures, 28, 129, 345, and, of course, 551, against the observed values of 54, 151, 354, and 551. Excepting the figures which must agree, these values are uniformly too small, so that a correction of the order of 10 per cent. suggests itself. Making this addition, one has for the forecast approximately 450, 290, 150 for the weeks ending January 21st, January 28th, and February 4th. In these weeks the deaths actually recorded were 443, 320, and 191. The agreement is not very close; it appears that the falling off of the present epidemic is more gradual than that of 1895, but it will be admitted that for practical purposes the result is not unsatisfactory, and it has the merit of being a genuine prediction, not, like so many prophecies, made after the event. It is, we think, quite obvious that epidemiological prediction must be guided by local precedents; that, so far at least as influenza is concerned, no universal arithmetical formula will be of service. Thus, to take only one example, the evolution of the epidemic in Newcastle-on-Tyne, where the successive weekly deaths from the week ending January 7th have been 5, 23, 82, 74, 42, has been quite different from that of London. A striking feature of the present epidemic has been its relatively greater intensity in the north-east of England and in Scotland. The maximum of the wave has also been reached later in the north, but we can hardly attribute the extra severity to the delay, because in the third wave of the 1918-19 pandemic northern England was much more severely visited than the south, but reached its maximum no later.

INFLUENZA.

THE Registrar-General's returns and such information as we have received from our correspondents suggest that, unless some abrupt change occurs, the epidemic will follow very much the course we indicated as being probable some weeks ago. So far as London is concerned, the epidemic has in fact been on similar lines to the outbreak of 1895. In Scotland, however, and the north-east of England (as noted above), the outbreak has been more serious and of the same order of severity as the third wave of the great pandemic. The world distribution of influenza cannot yet be accurately reported, but so far as present indications go, this recrudescence seems to be mainly confined to Europe. In Scandinavia influenza became

epidemic in the cities early in January. At Copenhagen there was an increase of notifications from 63 to 129 in the last week of 1921, then 845, 5,845, 8,896, and 7,955 were recorded in successive weeks. Stockholm reported 42, 259, 410 in the first three weeks of January. Notifications in Switzerland amounted to 136 in the week ending December 24th, to 872 in the next week, and then to 2,663, 4,106, and 6,343 in the following weeks. Of course notifications have no value as exact records of epidemic prevalence, but they serve to indicate the trend of events. We have no German statistics, but the epidemic is said to have been widespread and severe in the south of the country. We referred to the newspaper reports of influenza in Berlin some weeks ago, and have received no later information. In France the worst period is said to have been the ten days before January 20th. There is also evidence of epidemic influenza in Holland and Belgium; it is said to be of a mild type. An extremely interesting point is the epidemic position in the United States. It will be remembered that early in 1920 influenza appeared in the great American cities, and a considerable epidemic was experienced. The Ministry of Health issued a warning here, but, although there was a quite appreciable increase of deaths attributed to influenza and of notified cases of pneumonia, the increase reaching a maximum at the end of March, and although in certain institutions definite epidemics occurred, the population as a whole was hardly affected. The statistics of the same cities between the beginning of November, 1921, and the last week of January, 1922—that is, during the period of maximum prevalence in western Europe—show no trace of epidemic influenza, but we understand from a press telegram that in the first week of February there has been a large increase of reported cases in New York. It remains to be seen whether on this occasion America will enjoy the relative immunity which Europe experienced in the winter of 1919-20, or whether there has merely been a delay in the passage of the wave. We have seen no reports from India upon which any conclusions can be based, and influenza is not said to be epidemic anywhere in China.

VOCATIONAL SELECTION IN INDUSTRY.

THE importance of the principle of vocational selection in industry has long been realized in America, and we are gradually awaking to it in this country, but so far any practical application of the principle has been very haphazard and fragmentary. We therefore welcome the publication of Report No. 16 of the Industrial Fatigue Research Board, which is entitled "Three Studies in Vocational Selection," as it gives us an insight into the kind of observations which ought to be made in the selection of candidates for an industry, and some measure of the probable value of the tests employed. The first study, by Mr. B. Muscio, concerns the psycho-physiological capacities required by the hand compositor. At present the choice of an apprentice to the printing trade is usually made on the strength of a few inadequate tests as to his powers of reading, writing, spelling and grammar, and it is generally admitted that the procedure is unsatisfactory. It is said that many boys become apprentices who are totally unfit for the trade, and that as their period of apprenticeship is extremely long (seven years), it is specially important that, so far as possible, only boys with a natural aptitude for the occupation should be selected. In order to ascertain what qualities make for a successful printer, Mr. Muscio applied a series of carefully thought-out tests to groups of twenty-five compositors and determined the correlation between the skill they showed in performing these tests with their skill in composing. The grading of the compositors in order of merit was undertaken by the overseers, and the correlation coefficient between this grading and the ability of the men in the three most suitable tests tried by Mr. Muscio came to 0.71 in one instance and 0.62 in another (perfect correspondence yielding a coefficient of 1.00 and total lack of correspondence one of 0). There can be little doubt that if candidates for apprenticeship were

made to perform these tests a considerable insight into their natural aptitude would be obtained, and the poor performers could at once be weeded out. Selected apprentices, it is suggested, should be made to perform these and other tests at yearly intervals, as further insight into their abilities would thereby be yielded; we are not clear what action it is thought might be taken after this later information has been obtained. The second study deals with the measurement of physical strength in 2,300 youths ranging in age from 13 to 20. They were tested by Martiu's method, which has obtained a considerable vogue in America. Its aim is to determine the strength exerted by the subject in resisting a pull on certain groups of muscles, such as the pectorals, the forearm flexors, and the abductors and adductors of the thighs; the combined pull of these muscles was considered to afford a reliable index of muscular strength. About half of all the observations were made by one investigator, and half by another, and it was found that at each age group the test showed a 10 to 20 per cent. larger value at the hands of one investigator than at those of the other, though both of them tried to apply the test in exactly the same way. It follows, therefore, that the test is unsatisfactory for general use, and Mr. Muscio is of opinion that a much simpler and more reliable indication of general strength is afforded by the determination of the strength of grip (by means of a Smedley dynamometer), and combining it with the weight measurement. The third study, by Mr. Eric Farmer, describes the correlation in the proficiency with which girls could pack sweets, and certain physical measurements, such as span of hand and length of reach. As might be expected, the correlation was not large, though it did exist. Proficiency for the most part depends on other factors which cannot be obtained by physical measurement.

THE INVENTOR OF DOVER'S POWDER.

Among the members of our profession who have had a life of adventure—and there are many of them—few names are more familiar in our mouths than that of Thomas Dover (1660–1742), who, as Dr. J. Veun¹ pointed out in his series of "Academic Sports," took his B.A. at St. Mary's Hall, Oxford, and the M.B. from Caius College, Cambridge, and became a captain in a buccaneering expedition, in which capacity he in 1710 rescued Alexander Selkirk, whom DeFoe made immortal as Robinson Crusoe. Eventually Dover began the practice of medicine in London, where he became known as "the quicksilver doctor" on account of his cure for asthma and many other ills—namely, "an ounce of quicksilver daily to be taken at what hour the patient pleases, and a spoonful of the gas of sulphur in a large draught of spring water at 5 o'clock in the afternoon and at bed-time." In his well known collection of biographical essays, *An Alabama Student* (1908), the late Sir William Osler gave an attractive account of this "physician and buccaneer," with many details about his popular work, *The Ancient Physician's Legacy to his Country*, "designed for the use of all private families." To the February number of *The Bookman's Journal and Print Collector*, which we are given to understand is the only periodical in the world devoted exclusively to the collecting of books and prints, Dr. Philip Gosse, the son and grandson of leaders in literature and zoology respectively, contributes a brightly written sketch of Dover's adventures as a pirate, based mainly on a rather rare book, *A Cruising Voyage Round the World*. This book was begun in 1708, and, according to the title-page, contains "Remarkable transactions as the taking of Puna and Guayaquil, of the *Acapulco* ship and other prizes: an account of Alexander Selkirk's living alone four years and four months on one island, etc., etc., 1721," by Captain Woods Rogers, who commanded the expedition of two ships—the *Duke* and the *Duchess*—fitted out by the merchant adventurers of Bristol at the instance of William Dampier, the famous circumnavigator, freebooter, naturalist, and hydrographer. Dampier, then

56 years of age, went as pilot, and Dover, who was practising in Bristol, was chosen as second in command, not because he had any knowledge whatever of the sea or ships, but, strange as it may seem, on account of his bad temper; for it was shrewdly argued by the merchant adventurers, who were financially interested in the expedition, that Dover's vile temper would render him so unpopular that he would not have any followers should he attempt to break away from the main party—a danger that had led to the failure of previous expeditions in which a popular second in command had been persuaded by a discontented party to go off on a separate cruise. As may be imagined, the voyage was not free from quarrels over the distribution of the spoils. After sacking Guayaquil the English sailors stored their plunder in the churches and spent the night there to guard it, but their sleep was much disturbed by the smell of corpses recently buried as the result of an epidemic of "plague." Next day they returned to the ships, but within forty-eight hours 180 of the crew of one ship were down with the plague; here Dover stepped in and ordered the ships' surgeons to bleed every sick man to a hundred ounces, and to give large draughts of dilute sulphuric acid; it is recorded that this drastic treatment was justified by the recovery of all but eight patients. Dr. Philip Gosse concludes his interesting note with the remark that "Harley Street might be searched to-day from end to end and not such another found." This no doubt is true.

THE BEGINNINGS OF A CULT.

DISCIPLES of Sir J. G. Frazer and readers of the chapter on the cult of Asklepios in Dr. Farnell's Gifford Lectures of 1919 (recently published) may like to be referred to an account in George Calderon's fascinating book on Tahiti of a visit to a Tahitian village doctor. Calderon's native friend, Amaru, who had a sore throat his wife could not cure, arranged that he and Calderon should go together to get a remedy from a famous native doctor or Tiurai (Tahu'a Ra'au, literally priest) who lived in a village at some distance. As they approached the village at dusk they met a tall thin man walking rapidly in the opposite direction; this was the Tiurai, who had been giving consultations since early morning and had left his remaining patients in order to have a talk with a friend and rest himself. Amaru and Calderon sat down on the grass under some trees, where others who were waiting joined them. Presently the Tiurai returned, and, going into a yard at the back of his house, sat down cross-legged on a coco-nut leaf; he wore a hat with a kerchief over his head like the email of a helmet. The company sat round on tree trunks in a big ring, and the scene was lighted by a lantern on the ground. The first case was a baby, whose mother, a girl of 17, had, it was suggested, been guilty of some imprudence of diet. The father and grandfather told the tale of the illness, the Tiurai listening, exclaiming from time to time *E pa'i* (yes, yes). His manner was gay and debonair, and he made comments from time to time; others offered explanations, and all were in good spirits, amused by Tiurai's witticisms. He did not look at the patient, but told the father, who must himself make the medicine, to get some nono fruit and the midriff of a particular leaf, and boil them in water from a coco-nut no longer young; the father was made to repeat the instructions, and the family started off on its long journey home. Then Amaru described his sore throat and how he got it; without looking at it the Tiurai told him to mix a little wine with brown sugar and hot water in a bowl, to inhale the vapour and throw the liquor on the earth. All this Amaru did when he got home, and his sore throat was cured by the first inhalation. The Tiurai received no fees, rarely even presents; he was supported by his relatives. He is described as a lean, active man of sixty, but having the look of thirty, with a keen clever face. He was remarkable also as the only celibate among the Tahitians. One native doctor does not teach another; most villages have someone who advises the sick; and now and again a man of strong character earns general respect and becomes known far and wide as a healer. The Tahitians are an indolent people and

¹J. Veun, *The Caius*, 1907, xvii, 32–42.

seem to have little recollection of their ancestors. It is easy to conceive that with a quicker-witted people disposed to ancestor worship such a life as that of the Tairai described might easily become the basis of a cult. Dr. Farnell's view is that Asklepios was a man who, after his death, was remembered as a great healer, who then had a place among the heroes, was next worshipped as a god, and finally looked on as one of the chief of the gods. It is interesting, at any rate, to hear of the practice of a kind of incubation in Tahiti. Patients who went to the shrines of Asklepios were directed to sleep with an ear to the ground, when the earth god would tell them what to do to be cured. The term "incubation" is derived from *incubare*, to lie upon anything, and in classical times was used in the particular sense of lying on the ground in or near the temple of the god, in the expectation of receiving a message from him. Calderon tells of an old woman of another Tahitian village who was regarded more or less as a witch, but had a certain reputation as a healer. She did not see the patient, but divined who it was and from what he suffered; she cast herself down on the ground and had communion with the spirit of her own dead child. Calderon was only a few months on the island, and though he made a special study of the language his acquaintance with it was necessarily limited; moreover, he explains in several places how difficult he found it, owing in part to the frequency of adoption, to get a clear idea of the relationships recognized by the Tahitians. Possibly, therefore, the old woman was listening for an earth spirit, as did the Greek and Latin of old.

AN HISTORICAL DOCUMENT.

WHATEVER be the fate of the recommendations of the report of the Geddes Committee—and it must be admitted that from the taxpayer's point of view the omens, for the reasons given elsewhere, are not at present good—it will be recognized that, taken together, the first two parts now issued form a document of immense interest to readers to-day, and one to which the historian will turn to learn how Great Britain faced the aftermath of the great European war, provoked by the German Emperor and his advisers. Into less than 300 octavo pages the Committee has compressed a mass of financial statistics which could only have been brought together with the ready assistance of the Treasury. Moreover, before making its recommendations the Committee had consultations with all the departments so far dealt with. These departments are responsible for over 400,000 millions out of the huge total of 500,000 millions the ordinary supply services have asked for next year. Readers will find a careful analysis of the recommendations with regard to medical matters made by the Committee, and its reasons, in the SUPPLEMENT for this week, but the taxpayer who really wants to understand the whole situation will procure the volumes themselves.* The Committee laments the loss of Treasury control over all departments, and perhaps its most immediately practical recommendation with regard to public health and education is that the percentage grant system—a system under which the State repays a proportion, usually a large proportion, of the expenditure of local authorities on certain services—should be abolished. The Committee rejects the argument that the system stimulates the authorities to improve the efficiency of their services, and declares it to be "a money-spending device." The suggestion is that percentage grants should be replaced by fixed grants or grants based on some definite unit. The analysis, in the SUPPLEMENT, will be sufficient to convince the impartial student that the medical profession has no need to fear the verdict of the historian, who will observe the ready consent of the profession to a reduction in the capitation fees paid to it under the Insurance Act, amounting

altogether, in round figures, to one million a year. He will note also the tenderness and evident regret with which the Committee advises that there should be no increase during the coming year in the cost of such medical activities as are concerned with maternity and child welfare, the prevention of tuberculosis, and of venereal diseases, and with the welfare of the blind. Incidentally our imaginary historian will note the curious fact that of the five members of the Committee, three, including the chairman, are or have been concerned with railway management, and two with shipping. He will note further that two of the members are Peers and only one (the chairman) a member of the House of Commons.

"BIRTH CONTROL" IN AUSTRIA.

THE laws of Austria have hitherto declared abortion, attempted or performed by any person, whether medical or non-medical, a crime, unless proof was produced that the prospective mother was suffering from a condition which, according to the recognized rules of medical science, would be seriously aggravated by completion of pregnancy. The issue of the *Journal of the American Medical Association* of January 21st contains a note from its Vienna correspondent, who states that the socialistic parties have now obtained great influence and that one of their doctrines—that a control of births is very necessary—has been embodied in a bill introduced by female and male members of the National Assembly. The main feature of this bill, he says, "is the proposition that abortion before the completion of the third month should be free from law restriction if performed by a duly qualified medical person, and if the mother consents to the operation." Persons who attempt to induce abortion without the consent of the mother are to be punished, as is a woman who tries to induce abortion after the third month; it is to be a criminal act also to induce abortion with the consent of the mother before the completion of the third month, without the aid of a medical practitioner. The whole bill is framed in a way to enable any prospective mother to get rid of the foetus at an early stage of development, and casts upon the medical profession what looks very like an obligation to procure abortion at the mere request of the mother. It is therefore rather surprising to find our contemporary's correspondent commenting favourably on the proposal. He goes on to say: "It must be admitted that the adoption of this bill would mean a real relief for numerous hard-working, ill-fed women who at present, under the most unsocial conditions of housing, or rather overcrowding and semi-starvation existing here, must regard their eventual pregnancy as a serious danger and severe accident, for which the above law would be the only remedy. Of course, the old moral principles do not yet find their way to consent to this novel departure of the law; still it emanates from a real feeling of responsibility on the part of the politicians who have drawn up the report recommending the adoption of this bill as an advance in social development." It is curious to find that in Austria methods for the control of conception, about which there has been so much publicity in this country, should seem to be entirely disregarded in favour of abortion.

THE HALF-YEARLY INDEXES.

THE usual half-yearly indexes to the JOURNAL and to the SUPPLEMENT and EPITOME have been prepared and are now ready for issue. They will, however, not be circulated with all copies of the JOURNAL, but will only be sent to those readers who ask for them. Any reader or subscriber who wishes to have one or all of the indexes can obtain what he wants, post free, by sending a postcard notifying his desire to the Financial Secretary and Business Manager, British Medical Association, 429, Strand, London, W.C.2. Readers wishing to receive the indexes regularly, as published, should intimate this desire.

* First volume 4s. 6d., second volume 4s. 6d. Committee on National Expenditure. To be obtained through any bookseller 4s. and 3s. net respectively.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

Asylum Administration.—Mr. T. Thomson asked, on February 9th, whether, in view of difficulties in securing some of the evidence necessary to enable the Departmental Committee of the Ministry of Health to investigate completely charges made as to the treatment of asylum patients, Sir Alfred Mond would reconsider the desirability of recommending the appointment of a Royal Commission with full powers both of investigation into the present system and a recommendation as to the future treatment of all types of mental disorder. Captain Loseby asked a question on the same subject. Sir A. Mond, in a written answer, said that the question of the appointment of a Royal Commission was under due consideration. It would, however, necessarily involve a long delay before any practicable steps could be taken, and would postpone reforms which by general agreement he hoped might be introduced at an early date. In view of the necessity for an expeditious investigation into the allegations made by Dr. Lomax he had appointed a Departmental Committee. He was informed that neither of the medical members was, nor had been, associated with any asylum maintained out of public funds, nor was it correct to say that the chairman was in any sense a representative of the system criticized. He feared that it was impossible for him to obtain the services of any expert who had not already shown interest in Dr. Lomax's criticisms. He regretted that Dr. Lomax was not prepared to substantiate before the Committee the charges he had publicly made, and that the National Asylum Workers' Union had refused to defend their members against Dr. Lomax's charges; but he could not admit that either Dr. Lomax or they were entitled to dictate the composition of any tribunal or inquiry on the issues raised, for the appointment of which the Minister was solely responsible.

Medical Service at Willesden.—Mr. Gillis asked, on February 9th, whether Sir Alfred Mond was aware that the private medical practitioners of the Willesden district were attempting to bring professional pressure to bear upon the medical staff of the Urban District Council of Willesden, with a view to causing the cessation of the medical service that had been provided for the public by the district council; and whether he proposed to take any steps to protect the interests of the medical staff and to secure the continuation of those necessary public medical services which were so popular with the public. Sir A. Mond, in a written reply, said he had been in communication with the Willesden Urban District Council and the British Medical Association in regard to the medical services provided by the council, but he was not aware of any professional pressure being brought to bear on the council's medical staff by private practitioners in Willesden.

Disabled Ex-Service Men.—Mr. G. Barker, on February 9th, asked a question as to the large proportion of disabled ex-service men who came upon the local rates owing to their pensions being insufficient to maintain them. The Minister of Pensions replied that disablement pension was granted as compensation for disablement by injury or disease sustained in war service, and the amount of the pension was regulated solely by the extent of the disablement as assessed from time to time by a medical board with regard to medical considerations alone. Such factors as wages, earning capacity, employment, or unemployment were expressly excluded, with the approval of Parliament, from consideration for pension purposes under the Warrants and Regulations. Provision for the relief of distress caused by unemployment was made through other departments. Captain Loseby suggested that full disability pension might be given to men whose disability was 50 per cent. or more, and whose unemployment was obviously partly contributed to by that fact. Mr. Macpherson said he thought that would work in the long run adversely to the pensioner, because at present if a man had a disablement of 100 per cent. the department did not interfere, even though he were drawing £5 per week.

Housing Statistics.—Sir Alfred Mond, in answer to Mr. T. Thomson, on February 9th, said that the total number of houses completed by local authorities and private builders under schemes of financial assistance up to January 1st was 102,480. In addition 3,150 other dwellings had been provided by the conversion of houses into flats or by the conversion of huts or hostels. The number of houses in course of erection was 85,892, and the number not yet started was 29,778. The lowest prices approved for houses recently had been £433 for a non-parlour house with two bedrooms, £450 for a non-parlour house with three bedrooms, and £500 for a parlour house. The Government could not extend financial assistance to housing schemes beyond the limits announced last session.

Coroners and Juries Acts.—At the instance of Mr. Percy, on February 9th, Mr. Shortt said he hoped shortly to bring in a bill to continue the Coroners Acts, 1917, and so much of the Juries Acts, 1918, as related to coroners.—On inquiry by Mr. Walter Smith, on February 14th, whether the experience of coroners in holding inquests without juries had proved efficient and satisfactory, and whether steps would be taken to continue this method, Mr. Shortt said it was intended to introduce a bill on the subject at once.

Criminal Law Amendment Bill.—The text of the Criminal Law Amendment Bill, introduced by the Home Secretary last week, has not yet been printed. It is based on the Bishop of London's bill, which in the final stage near the close of last session had to be abandoned on account of differences between Lords and Commons on amendments, there not being time to consider the subject further.

Paris.

(From our Correspondent.)

INAUGURAL ADDRESS BY PROFESSOR E. SERGENT.

NEVER has the "Grand Amphithéâtre" of the Paris Faculty of Medicine, which, notwithstanding, has had a long experience, seen such a crowd as on January 12th. It came to hear the inaugural lecture of Professor Emile Sergent. The dean, Professor Roger, and the new teacher had to fight their way to their places, and the official procession had to submit to breaking the rules as to the compression of bodies. The enthusiasm of the audience for a long time prevented the holder of the new chair of clinical propædæutics¹ from beginning his address. The plaudits could be heard a long way off. It was not only that the students acclaimed a sympathetic teacher, it marked the beginning of the break up of the archaic system which has hitherto governed the selection of our professors.

M. Sergent, physician to the Hôpital de la Charité, is well-known by his work on syphilis and tuberculosis, on calcium metabolism, and in particular on adrenal insufficiency in infectious diseases. But, as he reminded us in this opening lecture, he had been an unsuccessful candidate at the examination for the position of associate professor (*professeur agrégé*). Professors have hitherto always been elected, by the Council of the Faculty, from among the *capables*, the sacrosanct body of *professeurs agrégés*. Now to the very same hall, in which he had suffered a check which had seemed to shut against him the gateway to a teaching appointment, M. Sergent returned clothed in the professor's red robe. The Faculty had broken with tradition, and had appointed him by a vote for which there was no precedent. What do the present *professeurs agrégés* think of it? If the possessor of that title is no longer to be a member of a close corporation the desire to obtain the title will quickly disappear. It is indeed to be hoped that in future the barrier between the Faculty and the men whom circumstances have kept away from the competition should not be insurmountable. It is to be hoped that in France, as in England, a man who has done good work may be able to obtain a teaching post.

The Académie de Médecine.

M. Sergent has, therefore, broken a record. It is not his first achievement of the kind, for in 1919 he was elected a member of the Academy of Medicine by a unanimous vote. Similar unanimity may be found to exist in the same assembly when Madame Curie comes up for election. I have already explained the position about this, and it appears that after a short discussion at a meeting of the Academy of Medicine, the principle that she might be elected was established by a sufficient majority, and the assurance is given that in face of this vote on the matter of principle, the other candidates will retire, leaving the field free to Madame Curie. An unforeseen and happy action of the salts of radium, that of opening the door of the Academies of France to women.²

PATHOLOGY OF INFLUENZA.

Professor Letulle has just communicated to the Academy the results of his investigation of the pathological anatomy of recent epidemics of influenza. The interesting point is the confirmation of the fact that the fatal pulmonary complications are not due to lesions of the nature of pneumonia. M. Letulle states that little foci of pulmonary necrosis occur around the bronchioles, and produce small abscesses; this observation is held to explain the rapid evolution of the disease to a fatal termination. Professor Besançon states that in the present epidemic patients have passed through the three usual stages—coryza, bronchitis, and pleuro-pulmonary manifestations—but adds that the latter seem to be less serious than on previous occasions. Nevertheless the number of cases is still large, although the hospitals which had made special arrangements to receive influenza patients have not had to put them in force. No relation can be traced between the hospital statistics and those of the big administrations, such as the postal services and the banks, the normal working of which has occasionally been affected. On the other hand, a parallelism is now, as always, to be traced between the

¹ Propædæutics is "the body of principles or rules introductory to any art, science, or subject of special study; preliminary learning."—*The New English Dictionary*.

² On February 7th Madame Curie was elected *membre associé libre* de l'Académie de Médecine by 64 votes and 15 "bulletins blancs." There was no other candidate.

importance of the paragraphs that the daily newspapers devote to an epidemic and the wish of the workman to give himself a little additional holiday. It would be interesting to compare the percentage of cases of influenza among employers and employees.

ANGLO-FRENCH RELATIONS.

We have been much interested by the formation in London of an International Society of Hygiene. Many members on our side of the Channel have joined it, for we joyfully take every chance of creating new ties between the nations. This week we have had the privilege of receiving Sir Almroth Wright at the meeting organized on the occasion of Dr. Netter's retirement from the Hôpital Trousseau. Sir Almroth Wright made a speech in French which went to our hearts. We have had also the pleasant surprise of meeting in Dr. Bahinski's clinic that great friend of the whole Parisian medical profession, Sir StClair Thomson.

New South Wales.

OUTBREAK OF PLAGUE IN SYDNEY.

SOME weeks ago a number of plague-infected rats were taken from a steamer which had arrived from Brisbane, where plague had been known to be in existence for some weeks previously. strenuous efforts were put forth by the Sydney Board of Health to secure the destruction of the rats on the wharves and foreshores. A few infected rats were subsequently found in a warehouse in Sussex Street, but for some time past no infected rats have been found. However, last week a case of suspicious illness was reported in a man who had been at work in the neighbourhood of the premises on which the infected rats had been found. This was subsequently proved to be plague, and the patient died at the Coast Hospital. Two days ago another case was reported, and this, too, has been proved to be one of plague. The Federal Health Authorities have declared Sydney an infected port; they are fumigating ships on their entry, and are supervising the loading of all cargo, excluding any that is rat-infested or is considered likely to contain rats. There is also a medical inspection of all people on board immediately before a vessel leaves port. The last outbreak of plague in Sydney was in 1900.

REGISTRATION OF MIDWIVES.

Several deputations waited on the Minister of Health recently offering certain suggestions with regard to the registration of nurses. The Council of the New South Wales Branch of the British Medical Association urged the registration and Government control of midwives. Dr. Fourness Barrington, the President of the Branch, contended that the maternal mortality was higher in New South Wales than in any other State of the Commonwealth. The statistician's reports showed that the mortality from puerperal fever and accidents of childbirth was 5.7 per 1,000 registered births, and in the metropolitan area it reached as high as 7 per 1,000 registered births. The registration and supervision of midwives was also necessary because a considerable number of confinements in New South Wales were in the hands of untrained midwives, and a proper registration and supervision of these midwives would result in a greatly reduced mortality rate. In reply, the Minister promised that in the Nurses' Registration Bill, which he still hoped to introduce in Parliament this session, he would endeavour to incorporate as far as possible the suggestions of the deputation.

A NEW HOSPITAL BILL.

The Minister of Health informed a deputation which waited on him recently that the Hospital Bill which was being drafted would provide that each worker could be called upon to pay 3d., each employer 3d., and the Government 6d. per month, and that each local district would have the power to impose this tax. He thought that such a measure as this would ensure that no one could escape paying his fair share towards the running expenses of the hospitals. Public charity could still be exercised in the direction of donations or bequests for extensions and improvements.

THE USE OF WHITE LEAD FOR PAINT.

A lengthy inquiry was recently held by the New South Wales Board of Trade into the question whether white lead

as used in the painting industry is so injurious to painters or other workmen engaged in this industry that it is expedient or necessary to regulate, restrict, or prohibit its use in paints. The Board concludes that white lead is a substantial cause of injury and death in painters and others engaged in the painting industry. Although the number of actual deaths from lead poisoning is not large, yet the amount of illness attributed to it is considerable. The attack rate among painters is not known, but among the miners at Broken Hill it has been found that in 9 per cent. of those exposed to dust containing lead sulphide and oxide the effects of lead poisoning have been marked. While the Board considers that determined action is demanded in the public interest, it does not feel justified in determining the details of the regulations on which the prevention of lead poisoning should be based. It, however, suggests that the regulations under the Factory and Workshop Act of Great Britain should be followed, such as the control of dust, the institution of periodical examination of workers, the suspension from the trade of susceptible persons and of those manifesting any of the early signs of lead poisoning, etc. While these and other similar measures must be applied to reduce the injurious effect of lead in the painting industries, the Board maintains that the damage caused must be measured and all the victims be adequately compensated.

England and Wales.

THE INFLUENZA EPIDEMIC AT MANCHESTER.

THOUGH influenza is still very prevalent in Manchester and the surrounding districts it is hoped that the crest of the wave has passed. The type has not been unusually virulent, but it has been serious on account of the large number of persons affected. In many cases whole families have been attacked, and business houses have been seriously depleted in numbers, whilst in some places work has been completely discontinued.

The present epidemic, when compared with the last serious visitation in 1918, shows a marked difference in mortality. This is due chiefly to the less fatal nature of the disease rather than a lower attack rate. Most of the deaths appear to have been due to pulmonary complications. The deaths in Manchester from influenza during the ten weeks ending February 11th were as follows:

For the week ending—									
December	10th, 1921	7
"	17th, 1921	7
"	24th, 1921	10
"	31st, 1921	13
January	7th, 1922	27
"	14th, 1922	24
"	21st, 1922	52
"	28th, 1922	37
February	4th, 1922	35
"	11th, 1922	33

The ordinary uncomplicated case has shown the following features. The onset is usually sudden with an attack of shivering; with this is commonly associated headache, pains in the limbs or lumbar region, nasal catarrh and a sore throat. Sickness was fairly frequent and sometimes ushered in the attack, and a troublesome cough was often present; other cases started with giddiness or faintness, occasionally actual fainting. A second type was associated with diaphragmatic pleurisy, but effusion was rarely seen. A more serious variety was marked by generalized bronchitis with frothy or purulent sputum and high irregular temperature. In these cases the duration of the attack was about two to four weeks, and resolution was by lysis. A fourth and still severer type presented pleuro-pneumonia of lobar distribution, nearly always involving the lower lobe. Here again there was frothy or purulent sputum and the attack was of longer duration. The cyanosis, seen so commonly in a previous epidemic, was rarely observed in the present visitation. Cases of a puzzling type have been seen where the patient exhibited congestion of the throat, enlarged submaxillary glands, desquamation of the tongue with enlarged papillae, and a rash of the scarlet fever type on the chest and abdomen. This, associated with running from the eyes and nose, has led to extreme difficulty in diagnosis, and many cases have been sent to the Fever Hospital as scarlet fever.

Dr. Niven, the medical officer of health, has had to set aside a special isolation ward at the Fever Hospital for these cases of "scarlatinal influenza." The diagnosis can only be made by an expert, and then perhaps with difficulty. In

these cases the puncta of the rash are larger than in scarlet fever, their colour is dull, and the rash does not appear in the usual areas attacked by scarlet fever. The fact that desquamation occurs adds to the difficulty. These rashes are not usually seen in the severe cases of influenza.

The onset has generally been sudden, but the sensational accounts of individuals collapsing in the streets have been greatly exaggerated. Gastro intestinal symptoms have not been common, and pneumonia appears to have been less frequent and less fatal than in previous epidemics, though bronchitis has been commonly found. If the individual has been able to go to bed on the first onset of the attack the results have usually been satisfactory and the temperature dropped to normal within the week. It is in patients who persist in working that fatal complications are to be feared. Many cases of the apparently mild type have been followed by severe constitutional weakness and marked depression lasting a week or two. In these cases convalescence is slow, and a slight cough often persists for some considerable time.

INFLUENZA IN LIVERPOOL.

Our Liverpool correspondent writes: The present epidemic of influenza, although widespread, is fortunately not so severe as was the case in November and December, 1918. Pneumonia of the septic type is not seen, and the majority of cases soon return to health. The onset is insidious, heralded by headache, suffusion of the eyes, and some photophobia. Faucial symptoms are characteristic and accompanied by cough, but there is no tonsillitis. Pains in the limbs are always present, and the sufferers express themselves feeling dead-beat, as if they had overtaxed their walking powers. Gastric symptoms have occurred, but are distinctly uncommon. The temperature varies from 101° to 103°, generally lasting three to four days, bronchial catarrh is present, and loss of appetite is quite a feature. Lysis terminates the majority of the cases, and convalescence is soon established. Skin rashes must be uncommon, for they have not been noticed by medical men who have had a considerable number of cases in their practice. It would appear that bronchitis and bronchopneumonia accounted for the deaths, many occurring in young adults and children of school age. The medical officer of health, Dr. Hope, had issued some time ago a memorandum on the subject of influenza which gave simple and straightforward instructions how to avoid the risk of infection and what measures should be taken if attacked. There is good reason for concluding that the public have profited by this advice, and have recovered from influenza without any special medical treatment. Nearly ninety of the elementary schools have been closed owing to the prevalence of the scourge. The mortality rate in Liverpool for the week ending February 4th was 38; for January 28th, 25; and for January 21st, 14. In the neighbouring towns of Birkenhead, Bootle, Southport, and Wigan an increase in the death rate from influenza has also been noted. The general impression among practitioners in the locality is that influenza is on the decline.

INFLUENZA IN NEWCASTLE-UPON-TYNE.

On January 4th influenza suddenly appeared in Newcastle and, after lasting till January 21st, it just as suddenly disappeared. As to how the disease reached the city it is impossible to say more than that it seemed to be part of a huge wave which passed northwards, through the Midlands, from the South of England. At any rate, the epidemic was at its height in London before it reached Newcastle and the large Yorkshire towns. Though its deference was sudden, it was fully ten days before things returned to the normal. During the period referred to the deaths from influenza and pneumonia were as follows:

Week ending:	Dec. 24	Dec. 31	Jan. 7	Jan. 14	Jan. 21	Jan. 28	Feb. 4
Influenza ...	0	1	5	26	79	76	39
Pneumonia ...	6	6	21	23	54	57	37

When the epidemic was at its height the death-rate of the city was twice the birth rate. Instead of being one-half of the birth rate at this time of the year it was quadrupled. When the malady announced itself, Dr. Kerr, the medical officer of health, with commendable promptitude got the day and Sunday schools closed. Much good was effected thereby. He decided, and properly, that the schools should be closed at once as a preventive measure before infection spread.

Children under 14 years of age, too, were excluded from cinemas. Child welfare centres were not closed, but their activity was diminished by the aggregation of mothers and children. Visiting to the Victoria Infirmary and the hospitals were stopped. In the early days of the epidemic, when there was a mild panic, the cry of the public was for freer ventilation of the tramcars and railway carriages. At first passengers did not object much to the draughts of cold air, but as time went on the call for fresh air and free ventilation became less clamant. The belief, too, had got abroad that it was the women who were engaged in outdoor work, such as policemen, tramcar conductors and postmen who suffered most, but facts did not support the contention.

So far as the influenza epidemic in Newcastle was concerned, it may be said that the gerin was less virulent, that the malady affected individuals for a shorter time, that severity of the illness declining on or shortly after the fourth day, and that although attended by considerable physical weakness, yet the debility was much less than in the epidemics of recent years.

THE UNIVERSITY OF LONDON SITE.

The Provost of University College, Sir Gregory Foster, gave a lecture on the University of London, its history, present resources, and future possibilities, last week, in the course of which he touched on the question of the proposed new site at Bloomsbury. At present, he said, the University worked through thirty-six colleges, including twelve medical schools and five theological colleges. Excluding the hospitals, which were really the laboratories of the medical schools, the thirty-six colleges occupied 212 acres. In addition, 7½ acres were occupied by residential halls, and the playing fields extended over 215 acres. Altogether, the University at the present had no fewer than 21,000 students. Nobody made so absurd a proposal as to concentrate all this work on one site. The area the Government proposed to give would provide among other things a site for the central offices of the University and for the removal of King's College. The central offices at South Kensington were neither central nor adequate. With a senate house, central offices, King's College, and University College all established to the north of the British Museum, there would be the beginnings of a university quarter. King's College must, at any rate be removed from its present cramped site, which did not allow it to extend in accordance with its needs. The scheme could be justified only on the ground that it would render increased educational efficiency possible; so-called economy was not a justification. At the meeting of the London County Council on February 7th, a motion from the Education Committee, advising the Council to press upon the Board of Education the desirability of carefully considering the large open area at Holland Park as the site of a new university quarter was opposed by Mr. Andrew Taylor, a member of the senate, on the ground that the site at Holland Park, which extended to sixty-eight acres, was too large for the purpose in view, which was merely to provide central administrative buildings, a convocation hall, and examination rooms. He urged further that it was too late to reconsider the Bloomsbury site, since the contract was signed: the Institute of Historical Research was already founded, and the building of another was in contemplation. From subsequent speeches by Sir John Gilbert and the Rev. Dr. Scott Lidgett it appeared that the Education Committee, while putting forward a recommendation in favour of Holland Park, agreed with Mr. Taylor's views, but that inasmuch as, in July last, the Council passed a resolution in favour of Holland Park, and had received only a formal answer from the Board of Education and no answer at all from the University Grants Committee, to which the recommendation had been forwarded by the Board, it was deemed to be the only dignified course again to press upon the Board the desirability of considering the Holland Park site for university purposes. On this understanding the recommendation was agreed to.

A KENSINGTON CLINIC.

We have received the following communication from Dr. Harold H. Sanguinetti, honorary secretary of the Provisional Medical Advisory Committee:

As is generally known, the Kensington and other divisions of the County of London Branch of the British Red Cross Society have developed clinics for the treatment of ex-service men with massage, electricity, radiant heat, and remedial exercises. Although, owing to the closing of the Fulham

Clinic, the Kensington division finds that its work for pensioners must continue for a further indefinite period, yet the executive committee recognize that within a comparatively short time there will not be enough of this work to justify the maintenance of the clinic, and they have, after consultation with some local representative medical practitioners, including the Mayor of Kensington, decided to open a clinic for the general public, members of which, however, will only be able to avail themselves of the services of the clinic on the recommendation of a medical practitioner. A medical expert in physio-therapeutics will be in charge of the medical and surgical side of the work, while the administration will be in the hands of the Kensington Division, B.R.C.S., who in professional matters will be assisted by an advisory committee of medical men. Fees will be charged on a graduated basis up to a maximum of 5s. per treatment, anybody able to pay more than this sum being ineligible for treatment at the clinic. The clinic was opened for civilians on February 3rd, the hours of attendance being from 2.30 to 9 p.m. At a time when the development of municipal clinics has aroused much opposition in the ranks of the medical profession it is to be hoped that credit will be given to the Kensington Division of the British Red Cross Society for its endeavour to further the interests of the general public, the medical profession, and the masses and masseuses. Moreover, some at least of the Provisional Medical Advisory Committee hope that this attempt of the B.R.C.S. to develop in conjunction with the medical profession a much-needed physical treatment centre may serve as an example of how clinics may most usefully be developed and suggest the solution of many difficulties now confronting the medical profession.

ORTHOPAEDIC SURGERY.

The formation of a Section of Orthopaedic Surgery of the Royal Society of Medicine was celebrated by a dinner on February 7th, when Mr. E. Laming Evans, C.B.E., F.R.C.S., President of the Section, was in the chair, and between thirty and forty members and guests were present. Among the guests were Sir John Bland-Sutton (President of the Royal Society of Medicine), Sir Anthony Bowly (President of the Royal College of Surgeons), Sir George Makins, Sir Arbuthnot Lane, Sir D'Arcy Power, Sir Thomas Horder, Sir Crisp English, Sir Harry Baldwin, Sir John MacAlister, and Colonel Pilcher, R.A.M.C. After the health of the King had been honoured Sir John Bland-Sutton gave the toast of the new Section, coupling with it the name of the President, who responded. The health of the guests, proposed by Mr. E. Muirhead Little, was acknowledged by Sir Anthony Bowly, and several other guests made brief replies in response to the call of the President.

LOCAL HOSPITAL COMMITTEES.

In accordance with Lord Cavo's recommendations, the Voluntary Hospitals Commission has taken steps to establish local hospital committees throughout the country. In many counties these committees are already at work and in others they are nearly complete. In only two counties has it definitely been decided not to establish committees. The Hospitals Commission desires to make it known that any applications for emergency grants required before the end of the present financial year (March 31st) should be made as early as possible. All applications must be made through the local committee for the area in which the hospital is situated. Hospital secretaries who are in doubt whether a committee has yet been established in their area should communicate with the clerk to the county council, or in the case of the larger county boroughs with the town clerk. The office of the Voluntary Hospitals Commission is at the Ministry of Health, S.W.1.

CENTRAL MIDWIVES BOARD.

At the last meeting of the Central Midwives Board for England and Wales Sir Francis Champneys presiding, three midwives were removed from the roll, one was censured, and one severely censured. It was announced that Miss Paget and Dr. Jarvis had been re-elected to represent their respective bodies for the ensuing year. It was decided that the Chairman, Dr. Fairbairn, Miss Paget, and Miss Haydon should represent the Board at a conference with the Ministry of Health on the subject of the administration of drugs by midwives. The Board agreed to send copies of its resolution on this question, passed at the meeting of November 17th, 1921, to the Secretary of the Association of County Medical Officers of Health and to the Town Clerks of Hull and Birmingham, from whom resolutions had been received expressing disapproval of midwives having the power to carry and administer drugs containing opium.

Scotland.

Dr. J. P. STURROCK has been appointed a medical commissioner to the General Board of Control for Scotland, in succession to Dr. John Macpherson, C.B. He was appointed a deputy commissioner of the Board in 1914, and had previously acted as assistant medical officer in several district asylums, and as medical officer to H.M. Prison, Perth, and medical superintendent of the Criminal Lunatic Department.

THE INFLUENZA EPIDEMIC IN EDINBURGH AND ABERDEEN.

Whilst the published statistics and the more or less official pronouncements on the epidemic of influenza would seem to indicate that the type of case is less severe than that met with in the 1918-19 visitation, the opinion of many general practitioners and hospital physicians who have been engaged in civil practice during both is that the present epidemic falls little short of the previous one in gravity, and actually surpasses it in extent. They point to the rise in the number of deaths due to respiratory and cardiac conditions which has accompanied the fatalities due to influenza and influenzal pneumonia, and they emphasize the instances in which whole households have been affected. Be that as it may, Dr. Maxwell Williamson, the medical officer of health, has said of the week ending January 23th:

"During the early part of the week the outbreak of influenza showed no evidence of abatement, and while the type of disease in general remained mild, there were a considerable number of cases accompanied by such complications as to necessitate removal to hospital. The reported complications consisted chiefly in pneumonia and acute bronchitis, and during the first few days there were a considerable number of deaths from these causes. These included 26 due to influenza, 53 to influenzal pneumonia, and 62 to pneumonia, some of which may have been due to influenza as a primary cause. During the latter portion of the week quite a substantial improvement has been manifest. The number of serious and complicated cases has daily showed a tendency to diminution. . . ."

In the following week, that ending February 4th, the improvement was continued. The total number of deaths, which had been 365 (or 45.1 per 1,000) fell to 321 (39.7 per 1,000); and the intimations of influenzal pneumonia, which had been 146, fell to 92. In the week ending February 11th the total number of deaths was 194 (23.9 per 1,000) and the intimations of influenzal pneumonia 41. On February 14th the prohibition regarding visitors at the Royal Infirmary and other hospitals was removed. In Edinburgh several different types were met with, including the classic, with high temperature, pains in bones and joints, and catarrhal states of nose, throat, and lungs; the gastric, with diarrhoea and symptoms suggestive of appendicitis; and the laryngopharyngeal, with little or no temperature, but with "pink eye" and middle-ear complications.

In Aberdeen the epidemic would seem to have been about a week later in reaching its height, for the medical officer of health (Dr. Matthew Hay) reported that for the week ending February 4th the notifications of pneumonia of influenzal or other origin had been 86 as compared with 58 in the preceding week and 31 in the third week of the year. The deaths from influenza and inflammatory lung troubles had been 59, 34, and 9 respectively. Young children and old persons had suffered most severely.

THE INFLUENZA EPIDEMIC IN GLASGOW.

The outbreak of influenza in epidemic form commenced in Glasgow during the first week of 1922, and spread with such rapidity that within a fortnight its dimensions were considerable. It is now, however, quickly declining, and few new cases are reported. So much publicity has been given in the lay press to the alarming and devastating character of the epidemic, even to the quotation of figures for Glasgow and neighbourhood which are liable to be misleading, that it may be profitable to record shortly the nature and scope of the outbreak, supported by illustrative figures obtained from the Health Department.

The prevailing type has been mild throughout, with rapid onset of headache, backache, a varying degree of pyrexia, and slight catarrhal signs in the chest. The duration of attack has been short—a two- or three-day fever—but rather more prolonged when the catarrhal signs were more pronounced. There were practically none of the severe and rapidly fatal cases such as were frequent in the 1918-19 outbreak, and no cases were recorded in which the dreaded

"heliotrope" cyanosis appeared. Cases of the abdominal or gastro-intestinal type occurred, but were comparatively infrequent. A few cases have shown rashes which have so closely simulated those of scarlet fever and rose measles in particular as to cause difficulties in diagnosis.

As is usual during epidemic periods many cases of severe chill (with or without pyrexia), tonsillitis, laryngitis, bronchitis, or pneumonia have been erroneously labelled "influenza," sometimes by the doctor, at other times without his aid having been sought. It must be remembered, in considering the question judiciously, that the prevailing climatic conditions have been such as would, apart from an epidemic, have caused a decided increase in the incidence of respiratory troubles. For these reasons it is obviously impossible to supply figures which will represent with accuracy the effects of influenza and its complications. It must suffice to quote composite figures which reflect the result of the epidemic on the regular statistics.

On the whole complications have been few, but an interesting occurrence might be noted in passing—namely, the infection in quite a number of cases of the accessory sinuses, or of the middle ear. The prevailing complications of the present outbreak have been respiratory in character, and the epidemic has been associated with a considerable amount of pneumonia, largely of the bronchopneumonic type, especially in the young and in the aged. Indeed, the pneumonia of the past few weeks may be regarded to a large extent as an exaggeration of the normal increase which occurs at this season of the year.

Figures obtained from the health authorities show that the general death rate reached its highest point during the week ending on January 21st, when the rate was 52.4 per 1,000. The following table shows the rapid ascent of the death rate to this exceptional figure and its subsequent more gradual decline. For comparison the rates are given for the corresponding period of the preceding year.

Death Rates—Glasgow.

Week ending	December		January				Feb. 4.
	21.	31.	7.	14.	21.	28.	
1921-22... ..	14.3	17.5	21.7	32.7	52.4	44.0	39.9
1920-21... ..	17.7	16.5	18.4	17.0	16.0	15.8	15.4
Total deaths 1921-22	275	350	422	678	1089	835	783

This increase in mortality rate was almost entirely accounted for by an increase in deaths from influenza, pneumonia, bronchitis and other respiratory diseases. A certain proportion also was the result of an outburst of measles, which meantime is prevalent in the city.

Noteworthy features of the epidemic period have been the comparative absence of fatal attacks in young adults, and the relatively high incidence of pneumonia in young children and in old people. This is strikingly illustrated in the accompanying table, which gives the age distribution of the deaths from respiratory affections (influenza, pneumonia, bronchitis, and other respiratory diseases) during the three weeks when the epidemic was most prevalent:

Age Distribution.

Years:	-1.	-2.	-5.	-10.	-15.	-25.	-45.	-55.	-65.	Total.
Week ending— Jan. 21, 1922 ...	131	126	53	8	2	21	59	94	117	611
Jan. 28, 1922 ...	102	105	52	4	0	10	55	72	119	519
Feb. 4, 1922 ...	67	68	33	2	0	4	43	59	96	372

It is of interest to add that pneumonia was often further complicated by empyema, which was almost universally of a streptococcal character.

The figures representing the number of notifications of cases of pneumonia (acute primary and acute influenzal) from week to week reflect very accurately the epidemic wave:

For week ending	
December 31st, 1921	114
January 7th, 1922	113
January 14th, 1922	357
January 21st, 1922	644
January 28th, 1922	602
February 4th, 1922	394

Throughout the epidemic period a considerable strain has been imposed on hospital accommodation for the treatment of pneumonia, etc., and large numbers have been admitted to general hospitals and Poor Law institutions in various parts of the city. The Public Health Department in particular found it necessary to increase rapidly its own accommodation, until, at the height of the outbreak, the number of beds available for the treatment of pneumonia was 330, and we have it on their authority that all cases so severe as to require hospital care and treatment were admitted.

SCHOOL MEDICAL WORK IN GLASGOW.

At the weekly meeting of the Glasgow Medical Lunch Club held on February 9th, with Dr. F. W. Martin in the chair, Dr. James Grant Andrew attended as the guest of honour. Dr. Grant Andrew has been a member of the Glasgow School Board and the education authority for ten years, and in his address to the club members he dealt with the medical inspection and treatment of school children in Glasgow. He contrasted the work of 1911, the year when medical inspection was first instituted, with that of 1921, showing its gradual development and increased scope during that period. He pointed out that the percentage of abnormal children—about 30 per cent.—was strikingly similar to that of ten years ago, and further that the defects in those children were practically the same as those noted in 1911. Not only so, but the proportions of these defects to the total were practically the same. Dr. Andrew then dealt with the advances in the work among mentally defective children. He stated that about 10 per cent. of Glasgow children required spectacles. With regard to general development he showed from statistics that neither in 1911 nor 1921 did the average of height and weight come up to the Anthropometric Committee's standard, which perhaps was too high. The treatment of necessitous cases had become a very important part of the work. In 1921 the following numbers were treated: Diseases of the ear, 1,853; diseases of the eye, 3,679; diseases of the skin, 9,542. Children were also treated for bronchitis, debility, anaemia, rickets, tuberculous conditions, etc. Further, 7,673 children received dental treatment. In reviewing the results of medical inspection and treatment during these ten years the lecturer stated that improvement in the condition of the school child was slowly but surely taking place. To some extent that improvement had been hindered by the war. The necessity for better housing and a purer air was still clamant, and he wished the corporation all success in their efforts to improve both conditions. The chief difficulty in the way of such improvement of the standard, both physical and moral, was the lack of money, which, in these days of national impoverishment and increased taxation, was proving an obstacle to further progress.

EDINBURGH VICTORIA HOSPITAL TUBERCULOSIS TRUST.

The annual meeting of the Edinburgh Royal Victoria Hospital Tuberculosis Trust was held on February 1st, with Sir Robert Philip in the chair. The annual report referred to the new Southfield Sanatorium Colony, the purpose of which was to provide accommodation for the more difficult type of tuberculous patients, who by reason of their special features and needs, did not readily find sufficient treatment elsewhere. Such cases were a source of anxiety and difficulty, and needed special treatment or more expert guidance than most sanatoriums and hospitals were prepared to give. Already a number of patients with aggravated and distressing disease had been treated at the Sanatorium Colony, and were now on the way to recovery. The benefits of the Trust were open free to all suitable applicants throughout Scotland, but the management committee looked with special favour upon appeals on behalf of the households of ex-service men and women. It was stated that during the past fifty years there had been a progressive decline in the death rate from tuberculosis, and latterly the rate of decline had been accelerated, especially in Scotland. In the twenty-five years from 1890 to 1915 there was a drop from 193 to 111 per 100,000 for Scotland. Sir Robert Philip said that this was the thirty-fifth year in which the operations which were represented now by the Trust had been going on. Tuberculosis occurred in every class, but there were cases which did not come under the statutory possibilities of treatment, and for such cases the Trust had stepped in.

ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

The members of the society met on January 19th, when a discussion was opened by Dr. George Williamson, Dr. J. F. Christie, Professor Marnoch, and Dr. George Rose, on that

part of the Hippocratic oath which reads, "Whatever in connexion with my professional practice, or not in connexion with it, I see or hear, in the life of men, which ought not to be spoken of abroad, I will not divulge, as reckoning that all such should be kept secret." There was a good discussion, in which some of the senior members of the Students' Medical Society, who had been invited to be present, joined. On February 2nd Dr. W. F. Croll gave an address, with lantern illustrations, on "Graphic methods as an aid to the diagnosis, prognosis, and treatment of cardiac affections." The subject was divided into (a) how the records are taken, (b) the normal records and their interpretation, and (c) graphic records of abnormal conditions. The address was followed by discussion.

Correspondence.

FATS AND GOITRE.

SIR,—In his lecture, "Fats in Relation to Goitre" (*BRITISH MEDICAL JOURNAL*, February 4th, 1922), Lieut.-Colonel McCarrison showed that, by his experiments on pigeons, he had established a relation between "fat thyroid-iodine" balance and goitre. His well known experiments on himself and others in India indicated that intestinal bacteria are determining factors. Dr. Plummer, alluding to the latter aspect of the question, is quoted by McCarrison thus: "The relation of the bacterial flora to the available iodine would explain the geographical description of goitre." McCarrison apparently accepts this opinion; but notes in modification of his previous views that not the toxic agency of the bacteria, but the possibility that they may interfere with iodine absorption, would be a suitable hypothesis.

In this connexion it is worth remembering that whilst much is known of results of deficiency in diets of vitamins, little has been ascertained of the biochemical conditions favouring or impeding their formation in edible substances in nature, and of factors governing their utilization in the human organism; and that before commerce disturbed crude and long existing transport arrangements for interchange of land products, beri-beri was credited with geographical limits in India and Ceylon. The Agricultural Department of India has shown that plants may reflect in their chemical constituents the scantiness in certain soils of salts of importance to the human system—for example, phosphates; and, further, that plants produced in poorly aerated soils suffer from absorption of "toxic bacterial products." Possibly, therefore, factors connected with vitamins which have yet to be traced will aid a comprehension of reasons underlying the geographical limits of beri-beri, which undoubtedly existed.

Similarly, the reasons for assigning to goitre geographical limits are incomplete. Formerly, soil and water were believed to be the guilty factors. To such possible links in causation or transmission are now added by McCarrison carefully proved data pointing to the necessity of study of the domestic habits, diet and environment of those affected, and the probably difficult task of identifying intestinal bacteria or protozoa peculiar to, or disproportionate in, the endemic localities. If recent work as to "glutathione" and chlorophyll indicates the advance line of thought in biochemistry, there must exist a far-reaching sphere for research in determining why, if excess of fats causes a relative deficiency of iodine, the prevalence of goitre therefore should have geographical limits. Were it not so, McCarrison would have found Madras "Chetties" were object-lessons of his views.

It is evident if the inhabitants of areas where goitre is endemic are to receive the benefit of the years of persevering research by McCarrison, a stage has now been reached when laboratory experts should undertake field work hand-in-hand with local sanitary officials in the effort to determine the possibly varying factors of causation within endemic goitre areas. An investigation of a whole-hearted character would link up agricultural chemistry and biochemistry with sanitation more closely than hitherto; and, whilst the solution of the goitre problem might well be looked for, there could hardly fail to be accumulated a mass of practical facts of communal if not of national importance, which years of diffuse laboratory work might not attain.

There are several localities in England where such research could be undertaken. Thus, McCarrison states that "simple

goitre is common in Oxford." The extent of prevalence in any part of the country is, however, a matter of surmise founded, as far as I can ascertain, upon clinical experience in public institutions and of practitioners, as contrasted with requisite house-to-house inspection. An approximation to results by the latter method is available from statistics compiled from records of a recruiting medical board in the Western Command in 1916. Of 7,404 men over 18 years of age, 27 were rejected solely owing to the bulk of the goitre with pressure symptoms. In the case of 202 others, the existence of goitre formed a contributory cause of unfitness. If, as stated by Osler, women are affected in the proportion of 6 to 8 of men, there should be no lack of material for investigation in certain areas near Chester, whence these men were forwarded for examination.—I am, etc.,

Hendon, Feb. 10th.

W. G. KING,
Colonel L.M.S. (ret.).

MENTAL HOSPITALS.

SIR,—I beg to assure you that this correspondence will cease, as far as I am concerned, with the following remarks upon one point, which I pray you of your humanity to pass. As far as I gather, the evidence is not yet judged to be conclusively as to the cause of the strange emptiness of beds in public mental hospitals—those 18,000 vacancies referred to by the Mental Hospitals Association and Dr. Octavia Lewin as existing in these sinister places. The conscientious reformers have surely grounds enough for letting an anxious public know that there is reason for fearing the worst. For the dread suggestion begins to take shape that the methods of Sennacherib, Genseric, and Attila, combined and brought up to date, have been employed in this gruesome business. It is lamentable that the parchmented commentaries of these and like great masters of the art of elimination should have been "spurious verloren." Who can doubt that otherwise precious information as to their methods of creating and maintaining vacancies would have been bequeathed to us, thus furnishing a useful clue to our earnest reformers.

It is true that the documents might also have revealed the system adopted by those great social economists for removing councils for reform and predestined flagellators of the existing order: but "sauce for the goose is sauce for the gander." I would not have the watch-dogs of civilization miss any of the possibilities in this matter: therefore they should know that there is a further suggestion afloat which attributes the shortage in question to the adoption of the more subtle procedure which Bonaparte is (probably falsely) credited with having applied in order to save his plague-stricken troops from falling into the hands of the Turks on the retreat from Saint-Jean-d'Acre; this being brought up to date, of course, and thereby exhibited with more damnable art and deadliness. Lord only knows what those asylum doctors are capable of!

On the whole, this startling deficit in the balance-sheet of the unbalanced is perhaps rationally explained, as is done by the Board of Control in their seventh annual report, for the year 1920. Unfortunately this would appear to be amongst the governmental and public authorities which, together with individuals concerned with mental hospitals and the treatment of the insane, are—as may be gathered from the leading article in your last issue—anaesthetized to the National Council for Lunacy Reform and the voligeurs who flit around them. Far be it from me to quote a passage from this report bereft of its context, but it is clear that the 18,000 vacancies are present and prospective. Far be it from me, likewise, to refer a fellow creature to a Blue Book (to be purchased for 2s. 6d.) whilst Anatole France and other delectable Gauls continue to provide us with yellow books, even should the exchange turn against us.—I am etc.,

EDWIN GOODALL.

Cardiff City Mental Hospital, Cardiff,
February 13th.

SUICIDE IN BORDERLAND CASES.

SIR,—The question of suicide is closely bound up with the whole rationale of detention. The aim is naturally to secure the safety of the patient. But the point is to go a step further back and prevent the suicidal tendency. Far be it from me to encourage the throwing away of life with its myriad opportunities; especially since as we, children of a day, are so little able to estimate the full worth of what we throw away. To subject depressed cases to conditions infinitely more depressing seems to me the reverse of curative. I am

in misery does not appear to the victim worth preserving. It might almost be said that in some cases the severe regimen of mental institutions manufactures suicides.

From my position as medical adviser to patients drawn from quite a number of such institutions I have been impressed with the extreme sensitiveness of these patients to the taint connected with detention—a taint which is likely to cling to them through life, and even to prove a barrier to their returning to their former avocations. This stigma is stressed by the Lunacy Board, when it refuses to accept as evidence the testimony of one who has once been certified as to what befell him while under detention. In the absence of first-hand information secrecy reigns, and with it the encouragement of tyranny.

It is the easiest thing in the world to get a person into an asylum, and most difficult to get him out. The "delusions" alleged are often altogether harmless. The frivolous reasons for which people are in many cases committed are well-nigh incredible. The asylums receive all with open arms. Yet the board professes to be not only the protector of the helpless but the critic also of the grounds upon which they have been committed. When has the board ever invalidated a certificate drawn up on inadequate grounds or illegally obtained? Budgets of letters reach me continually from the friends of patients entreating for enlightenment as to how to get their relatives out or to prevent them going in. Thousands are consigned to asylums for no other reason than that no alternative place exists to which they might go voluntarily as to a harbour of refuge when but slightly unstrung. Professor G. M. Robertson admits that "there is nothing in the world to prevent the treating anywhere of those who do not need to be certified." But homes for such cases must be kept free from any link with the Lunacy Board, so that patients may not be afraid to enter them.

I have never proposed to do away with asylums. Everyone who can be proved to be dangerous or unfit to be at large ought, in my view, to be properly certified; and asylums ought to be kept for those only who are so certified. The section of the Scottish Act recommended by Dr. Robertson and Dr. Luke, which professes to evade certification, does not dispel secrecy, and is a serious menace to liberty. It permits absolute detention for six months on the sole authority of one doctor, without provision for inquiry or appeal.

I have followed the late Dr. Mercier in the conviction that the safest track to pursue in the study of aberration of the mind is to interpret the abnormal by the normal, and to carry out, in the treatment of unbalance, the common-sense method of giving special attention to its beginnings, and adopting natural and cheering adjuncts to recovery—in lieu of the vacancy, repression and intimidation which are at present distressing features in many mental institutions.—I am, etc.,

February 11th.

S. E. WHITE.

PREVENTION OF VENEREAL DISEASE.

SIR,—We are surprised that the letter published last week really contains nothing more than has frequently appeared in various journals and in Sir Archdall Reid's own book. However, there are so many deviations from accuracy that we should like to correct them, and in turn to ask your correspondents some questions which seem pertinent.

1. Your correspondents state that "the Royal Commission, in commending the National Council to the Government, commended itself." The National Council was founded in October, 1914. No member of the Royal Commission had any connexion with it until after the issue of their Report in 1915. Invitations were first extended to the ex-members of the Royal Commission in February, 1916.

2. They say that "lecturers of the National Council are forbidden to mention prevention." The instructions to lecturers on this point issued in 1919 are quite definite:

"That while this committee does not recommend any change in the policy of the Council with reference to the use of prophylactic packets, they would urge that in the Council's propaganda more stress should be laid on local cleanliness immediately after exposure to the risk of infection." "Such preliminary cleansing could not be confused with treatment, nor does it absolve the person from seeking medical advice at the earliest moment."

The pros and cons of self-disinfection are freely discussed at all men's meetings, and questions invited.

3. Sir James Barrett's "manifesto" is used in

James Barrett's own account¹ will show this complete po in Egypt with the addition, as one among many measures prophylactic packets in Cairo. He mentions Lieut.-Col. Elgood's experiment in Port Said as follows:

"(i) Rigorous repression of public indecency, unnatural offences, the suppression of pimps, the control of advertisements, and restriction of the sale of alcohol. (ii) Continuance of the system of medical examination of prostitutes. (iii) Provision of ablution rooms and the supply of prophylactics. (iv) Moral and hygienic lectures, guides to meet trains, and the like."

"With all these activities he gradually realized that venereal disease continued on a large scale, and he then followed the conclusion of the Cairo Committee and authorized the ablation plan. The result was that of 9,232 men who passed through local rest camp 4,580 reported exposure, and there were 15 infections."

Subject to correction by Sir James Barrett, we interject the ablation tent plan as a system of disinfection by or under the supervision of trained attendants—a system, that which has frequently been derided by your correspondents as impracticable for the civil community.

4. "While the disease in the rest of the country had risen from 36 to 64, that in Portsmouth Town had fallen from 54 to 54, and in the area to 47." Sir Bryan Donkin and Archdall Reid make much of the difference between venereal diseases rate for the Portsmouth area and that of United Kingdom in 1919.

Reference to the White Paper² from which they quote shows that the rate of 64 for the United Kingdom included Colon Royal Air Force, and all officers (even, naturally, those in Portsmouth area), while the rate quoted for the Portsmouth area excluded these branches of the Service. It is, of course, known that the Colonial rates were considerably higher than those of the British Army and landed the United Kingdom rate unsafe. The rise in the rate for troops in the United Kingdom from 1918 to 64 in 1919 is easily explained by the importation of disease by troops returning from abroad. It is well known that, after Armistice, the venereal diseases rate rose very greatly in armies abroad. Further, in response to a request by the National Council for Combating Venereal Diseases, the army authorities made some efforts to retain for treatment men found to be diseased and such retained cases must have been counted against a rapidly diminishing strength. Clearly the rate of 64 for the United Kingdom cannot be compared with those of 54.4 or 47.3 Portsmouth and Portsmouth area. As has already been said in Parliament, it is impossible to base any conclusions on rate 1919 because of the very rapid movements of troops, into country from abroad and out of the army on demobilization. White Paper giving these figures appears to have been published solely in response to a demand by Lord Willoughby de Broke.

5. Your correspondents infer that Southampton was main port of entry for troops in 1919. Our recollection that in that year troops were sent home mainly through Folkestone and Dover, even in the case of troops from East, who were demobilized at Marseilles.

6. They assert that the "ingenious statistician of the Ministry" supplied figures—(a) to the Interdepartmental Committee, (b) to Lord Sandhurst, and (c) continues to supply the National Council for Combating Venereal Diseases with its statistics.

As to (a), Lord Astor's report shows that the figures given were from a number of official sources; (b) we know, and it is strange if Sir Archdall Reid and Sir Bryan Donkin do not also know, that these figures neither originated nor were calculated by anyone connected with the Ministry of Health; (c) any statistics quoted by the National Council, whether British, are from official records, but, whenever possible in this controversial matter, they are taken from countries where the controversy does not exist, or from countries where experiences gained here among the civil population.

We should like to ask your correspondents for answers to the following questions:

1. Will Sir Archdall Reid publish what were the total admissions to hospital of venereal cases under his medical charge before as well as after he initiated his plan of disinfection at Portsmouth? Alternatively, can he say how many cases of venereal disease originated in his barracks before his method was introduced? Unless these figures are available there is no basis of comparison for those already quoted by him after his campaign commenced in 1917.

2. Will Sir Archdall Reid also indicate how many men in Portsmouth during the period of his experiment were admitted to other hospitals for venereal disease contracted while in Portsmouth and how many consulted private practitioners, a course which was pursued by some?

¹ Management of Venereal Diseases in Egypt during the War, BRITISH MEDICAL JOURNAL, February 1st, 1919.

² Statement made by the Ministry of Health, with concurrence of

3. On what evidence is the statement based that throughout the Portsmouth area disease fell to "vanishing point"?

4. Can Sir Bryan Donkin and Sir Archdall Reid explain why the authorities of the European armies are still keenly exercised as to how the present high venereal rate can be reduced, when, according to them, methods of self-disinfection which they claim are effective were "quickly adopted" after 1935?

5. Why is it that, after six years of propaganda in Germany on the lines suggested by the Society for the Prevention of Venereal Disease, there is no indication of the disease having reached the "vanishing point" in that country, but there is an undoubted increase among juveniles?

6. Can Sir Bryan Donkin and Sir Archdall Reid explain why several medical members of the Royal Commission received no indication whatever of a desire to bring the question of self-disinfection in men before that body; and why if any medical men wished to do so, and felt it important, they did not carry out their duty and insist on the evidence being taken, when they were examined as witnesses?

7. Can Sir Archdall Reid explain why they ignore salvarsan treatment as a factor in the reduction of the venereal disease rate which is apparent in the army and navy statistics of all countries from 1913 onwards, but is claimed by them as entirely due to self-disinfection?

8. Are your correspondents willing to submit to the analysis and criticism of an independent statistical expert their figures in support of the statement that in India, Egypt, England, France, the Cape and West Indies, where methods of self-disinfection were adopted, "among the soldiers so instructed disease invariably fell to 'vanishing point'?"

9. What form of instruction for civilians does Sir Archdall Reid advocate, when 25 per cent. of the patients attending the clinic at the Lock Hospital have used the methods of disinfection advocated by the Society for the Prevention of Venereal Disease?

10. How do Sir Bryan Donkin and Sir Archdall Reid consider the civil population should be instructed—whether (a) by posters, leaflets, and handbills, displayed to the general public; or (b) by lectures and intimate personal instruction to all adolescents? If the latter, at what age should the instruction be given?

11. Do your correspondents advocate that every civilian should receive repeated personal instruction on the technique to be observed, and always carry on the person disinfectant outfits for emergency use?

Notwithstanding all Sir Archdall Reid finds to say in depreciation of the work of the National Council, it remains true that in those districts where its educational campaigns have been carried through, and where the treatment clinics are well and efficiently run, there is already evidence of a very definite decline in the incidence of new cases of venereal disease, partly, we believe, a natural fall due to the termination of the war period, to strikes and commercial depression, but partly also to a higher standard of public enlightenment and the abbreviation of the period of infectivity resulting from the modern method of treatment.

While we think it regrettable that Sir Archdall Reid and Sir Bryan Donkin find it necessary always to impugn the *bona fides* of those who have arrived at different opinions from their own, we share with them the desire they express for an inquiry; but we believe that the experience gained during the last five or six years in various parts of the world would enable several fresh methods to be adopted, and we should warmly welcome the appointment of a second Royal Commission to inquire as to what further steps can be taken towards the prevention and treatment of venereal disease. Such an inquiry would *inter alia* terminate this unfortunate controversy, which has, by dividing the forces and confusing the lay mind, certainly retarded in England the campaign against venereal diseases.—We are, etc.,

E. R. TURNER,

Chairman, Medical Committee,
National Council for Combating
Venereal Diseases.

CHARLES GIBBS,

Surgeon to London Lock Hospital
and to Charing Cross Hospital.

London, W., Feb. 15th

SIR,—In your issue of February 11th I notice a letter from Sir Bryan Donkin and Sir Archdall Reid purporting to show that in my speech on November 14th, 1921, to the National Council for Combating Venereal Diseases I made "many misstatements and misinterpretations of facts."

I do not propose to make the same exorbitant demands upon your space. Their very long letter is nothing but a restatement, in their own partial way, of old facts. My speech was devoted to new facts. I gave figures and other evidence from many countries to prove my contention that, broadly speaking, wherever the policy of immediate self-disinfection had been actually tried it had failed. These facts they do not attempt to answer; the latest date I can find mentioned in the three and a half columns is February, 1920, and the

great bulk of their remarks applies to their view, well known and often stated, of events in 1916-19.

In the final two lines of their letter they say that the National Council can easily prove its *bona fides* "by joining the Society for the Prevention of Venereal Disease in a demand for a public inquiry conducted, not by officials, but by men of independent standing." No one knows better than Sir Bryan Donkin the efforts which I have made in this direction, for it was with him that I had several interviews upon this very subject.—I am, etc.,

London, S.W., Feb. 11th.

GORELL.

SIR,—There are one or two points in the letter by Sir Bryan Donkin and Sir Archdall Reid in your issue of February 11th from which I venture to differ.

In the first place the following sentence embodies a partial misstatement of fact, "... large bodies of Americans, Colonials and R.A.F. who did not belong to the British army, were not instructed, and were highly infected." This leaves the impression that no measures were taken to obviate the spread of venereal disease among the overseas troops. The area cited in the letter where these troops were located included practically all the Australians in England, and hence at least half of the "Colonial" troops referred to. Of the Americans I know nothing, but of the Australians I can speak with authority, because I was senior medical officer in different Australian Command Depôts in that part of England from January, 1918, until August, 1919.

From 1917 until the Australians finally left England, what is probably the most thorough campaign against the spread of venereal disease that has ever been attempted on a large scale was successfully carried out in the Australian camps in this country. The measures included early detection of deliberately hidden cases, early treatment, and prophylaxis by the compulsory issue of disinfectants, accompanied by both printed and verbal instructions in their use to all men proceeding on leave, and, in addition, there were ablation depôts in all the camps, and there were frequent lectures by medical officers on prophylaxis. The regulations governing this work were promulgated as orders, and as such were rigidly enforced. The carrying out of these orders was thus not left to the haphazard method of more or less voluntary and unofficial effort, which the writers indicate was in vogue in the British army. These regulations were, in my opinion, far more comprehensive, and therefore correspondingly more effective, than the efforts of Sir James Barrett in Egypt, about which the writers speak in glowing terms. I therefore presume it is through ignorance of the conditions existing among the Australians in England that they have not been quoted.

In the second place, they take exception to the use of the words "early treatment," which they define as "the equivocal teaching of delayed disinfection." No doubt this is a correct definition as regards their use in the British army, and as such I quite agree would certainly do more harm than good; but in the Australian army in England "early treatment" had a literal and very real significance, clearly differentiated from disinfection, whether delayed or immediate, and as such was a measure of proved value in cutting short the duration of an attack of gonorrhoea. The letter referred to below indicates that "early treatment" according to the Australian definition consisted of much more than "permanganate of potash in pails and calomel cream in pots," and that the results obtained were surprisingly good. This early treatment was not left to the men themselves, but was carried out by specially trained orderlies under the constant supervision of a medical officer. In the light of the proof of the value of this form of treatment that we obtained among the Australian troops I cannot subscribe to the statement, "whenever and wherever the latter (early treatment) has been practised there has been relative failure."—I am, etc.,

P. A. MAPLESTON, M.B.

(Late Major Australian Army Medical Corps.)

Liverpool, Feb. 15th.

THE CURE OF CANCER.

SIR,—The conditions attached to the offer of rewards—now amounting to £50,000—to be given to anyone discovering a cure for cancer were that the remedy was not to be surgical in its nature, and that the discovery was to be made within

¹ Treatment of Acute Gonorrhoea: Massage-Pack Method. By J. P. Fogarty, M.C., Major A.A.M.C. BRITISH MEDICAL JOURNAL, March, 1919, p. 215.

the ensuing five years, the decision as to the efficacy of the remedy being left to the Royal Colleges of Physicians and Surgeons of London. The medical profession is, I believe, grateful to the generous donors, who have modified the conditions originally imposed, so that now successful cancer research workers may receive rewards so far as these funds go.

The donors made their gifts in the confident hope that the rewards would be earned. The conditions at first attached were such that it is all but morally certain that the donations would have lapsed. It is more than likely that the limitation originally imposed in regard to the method of cure would have militated against the acquisition of the reward. It is possible that in the course of investigation some fortunate worker may discover a method of arresting the development and extension of cancerous growths without actually finding a means of eradicating them; an inquirer whose work led to this would be immortalized, and, although deserving of the highest reward, would have had no claim for any part of the gifts under consideration. The introduction of a time limit to the discovery of a cure was another serious drawback to the proposed reward.

In a morbid process so protean in its nature and so shrouded in mystery as cancer it seems problematical if anything would be achieved by the empirical use of one remedy after another in search of a cure, though it is just within the range of possibility that some such remedy may be found by a stroke of luck.

It would be a more promising investment as regards discovering a remedy to make all such gifts to cancer research institutions with well-founded reputations, such as the laboratories in the Middlesex Hospital and the Cancer Hospital, the funds so allotted being used in any way the directors of these institutions considered best. Those who have devoted a good part of their lives to the investigation of all phases of the cancer problem are more likely to know the most useful way of using such funds. Perhaps an increase in the number of cancer research scholarships is one direction in which further hope lies. It would appear that if ever a cure is found for cancer it will only be by patient and persevering inquiry carried out probably over a long period. Another means of helping in the finding of a cure would be that of giving prizes to persons who had advanced our knowledge of the etiology and pathology of cancer or elucidated any phase of the cancer problem that opens out a hope of discovery of a cure in the future. The adjustment of claims in these directions would be extremely difficult and probably could only be carried out equitably by cancer experts of the highest reputation.

Where the object is to reward individual merit in cancer research work I should be disposed to advise the creation of a special fund from which any Britisher (including workers in the Dominions overseas) who has advanced our knowledge in connexion with cancer in a practical way would receive a reward. This reward might take one or more of several forms—prizes, scholarships for investigation to be renewed in cases in which the work done is promising, and in other ways. I should make this into a specific cancer research reward fund, and keep it quite distinct from other allotments in connexion with cancer work.—I am, etc.,

P. HEHIR,

Westward Ho, N. Devon, Feb. 7th.

Major-General I.M.S. (ret).

GLYCOSURIA OF MALARIAL ORIGIN.

SIR,—When Dr. Harrison (*BRITISH MEDICAL JOURNAL*, October 22nd, 1921, p. 630) states that he prefers the diagnosis "Glycosuria of malarial origin" to that of "Very mild diabetes mellitus in a malarial subject," one naturally asks, Why not adopt the non-committal diagnosis of "glycosuria in a malarial subject"? In that case there might not be much reason to object, although, by the way, it is hardly proved that the individual in question ever had glycosuria. It is stated that sugar was found in his urine while he was in India, but the tests employed are not indicated. In England "glucose" was apparently found once only in his urine, in very small quantity, and even then the reader is left in doubt as to whether the reducing substance was "glucose," as no gas was produced by the fermentation test and no polariscopic rotation was observed. As to the malarial origin, no proof whatsoever is given. The individual had suffered from malaria, but no connexion between the two conditions is shown. On the other hand, there was a history of diabetes in his family. The question whether glycosuria may be due to malaria

infection is very interesting, but by no means new. It is surprising that Dr. Harrison has not found any reference to this matter in textbooks, as practically all books on malaria or tropical diseases in general deal with it. It has been asserted by some writers that glycosuria is of very common occurrence in malaria, but most recent authors are of opinion that the opposite is the case; in several well-known books it is stated that reducing substances are often found in the urine, and that their presence may have given rise to the erroneous diagnosis of glycosuria.¹ Laveran, Ziemann, and others, are of opinion that no causal connexion has been proved to exist, but a few authors give histories of cases in which it might be suspected. An interesting case is that described by Nannyn² in which there is a full clinical observation of the diabetes and a reasonable suspicion that malaria might be the etiological factor. Still more interesting are the two cases published by Castellani³ in which the diagnosis rests essentially on the fact that a cure was effected by the administration of quinine without any dietetic treatment.

This is scanty material on which to build any theory as to the nature of such a causal connexion. As Nannyn suggests, the frequency of liver affections and the likelihood of pancreas affections in malaria would make one think of malaria as an etiological factor in diabetes, but the rare coincidence of the extremely frequent disease malaria and the not uncommon condition of glycosuria tends to dismiss any idea of its being a factor of importance.

During a fairly long tropical experience in various parts of the world I remember no cases of glycosuria in which I had reason to suspect malaria as the cause. On the other hand, I can fully confirm the observations just mentioned on the frequent occurrence of reducing substances in the urine, other than glucose, with the qualification that I have frequently observed reduction of Fehling's solution in the urine of Europeans in the tropics whether they had suffered from malaria or not. This is not at all surprising considering the frequently increased concentration of the urine, owing to excessive perspiration.—I am, etc.,

HAROLD SEIDELIN,

Médecin principal des Huileries du Congo Belge.

Kinshasa, Belgian Congo, Jan. 9th.

TREATMENT OF SQUINT.

SIR,—It may interest Colonel Henry Smith, of whose hospitality and work at Amritsar I have most pleasant recollections, to hear that work on somewhat similar lines is being carried on in my clinic at the Western Ophthalmic Hospital.

I use a faradic coil, kindly lent me by X-Rays, Ltd., which is a modification of the Bergonié apparatus, designed particularly for the treatment of small surfaces. By means of a sliding coil and a switch controlling the voltage, four different voltages may be used; the interrupter is designed to give a fine wave form of current, gradually varying in intensity, and the speed of the impulses can be adjusted as required.

I have been impressed with the fact that success in advanced operations, other things being equal, is proportional to the development of the advanced muscle. If the muscle—for example, the external rectus in convergent strabismus—is thin and badly developed, a poor result may be anticipated, and I was consequently led to try to improve the nutrition of the muscle by regular electrical stimulation before operation. The passage of the impulses is not attended with much pain, but is extremely unpleasant, though I have not seen vomiting or other disagreeable after-effect. My results so far have not been satisfactory, largely perhaps because I have not yet succeeded in finding the most suitable form of electrode.—I am, etc.,

London, W., Feb. 7th.

A. RUGG-GUNN.

SPINAL ANALGESIA AND GENERAL ANAESTHESIA.

SIR,—In the *BRITISH MEDICAL JOURNAL* of January 28th, p. 165, Dr. Battye refers to "local and spinal analgesics which at one stroke abolish nearly all the dangers and disadvantages of general anaesthetics, whether new or old." As Dr. Battye was referring especially to ethanesal, of which I have had some experience, may I be permitted to suggest that his remarks require some qualification?

¹ See, for instance, Mannaberg-Stephens, "Malaria," in Nothnagel's *Encyclopaedia*.

² *Diabetes Mellitus*, 1905.

³ *BRITISH MEDICAL JOURNAL*, August 20th, 1921.

In England and America the immediate mortality of spinal analgesias is more than twice that of general anaesthetics. I know of a series of 200 spinal analgesias in which two died on the table, while a third was only saved by immediate direct cardiac massage. The most careful technique was employed in all these cases, and the calculated minimum dose of freshly prepared "light" storaine was used. None of these cases showed any signs of ascending paralysis, but apparently suffered from primary cardiac failure due to the injected drug. It is true that local and nerve blocking analgesias are much safer, but even so, I know of a child who died from novocain poisoning.

Passing now to the after-effects of these different methods, careful observations were made at a military hospital, where about half the cases were operated upon under general anaesthesia and the other half under local or spinal analgesia. It was found that as regards pulmonary complications there was nothing to choose between these methods, but that vesical atony, persistent headache, and paresis of the legs occurred after some of the spinal cases. It was also found that novocain gave rise to less toxic symptoms than did storaine, but unfortunately the muscular relaxation was not nearly as good. These comparisons were obtained with the use of ordinary chloroform and ether as supplied to the army, but with the use of better technique much finer results can be obtained. For instance, it is quite common for a patient to have an hour's operation under a gas-oxygen-ethereal combination, and to enjoy a cup of tea within an hour of its completion, the after-effects being negligible.

In view of these facts I should hesitate to describe an inhalation anaesthesia as "little short of a surgical catastrophe."—I am, etc.,

London, N.W., Feb. 7th.

C. LANGTON HEWER.

THE DETERMINATION OF SEX.

SIR,—In your issue of January 28th (p. 157) is an article headed "The Determination of Sex," which discusses a paper by Mr. Huxley read before the Society of Arts. I observe that Seigel's work is referred to, and it is suggested that the control of sex might be achieved if his rule were followed. This deduction might be justifiable if Seigel's conclusions, published in 1919, and an extract of which appeared in the JOURNAL (Epitome of Current Medical Literature), were true in fact. Seigel, however, in 1921, changed his opinions, and an epitome appeared in one of your issues for September. The conclusion he now draws is that the statistical differences of the period of gestation are dependent upon the fact that the boy is five and a quarter days older at birth than the girl.

I suggested this explanation in your correspondence column in 1919, and I think there can be little doubt that the whole weight of evidence bears out this conclusion. It cannot therefore have any bearing on sex determination. The point is of interest, because it necessarily suggests that the cause of labour must be looked for in the child and not in the mother. It would suggest, in view of the extraordinary influence that pituitary extract has in hastening the birth, that it is in the pituitary gland of the embryo that we must look for the origin of some substance which, passing into the circulation of the mother, causes the uterus to contract. On this hypothesis, extract of pituitary gland from immature offspring previous to full time should be inactive, whilst that prepared after the birth of the animal should be potent.—I am, etc.,

R. J. EWART,
Medical Officer of Health.

Barking, Jan. 31st.

THE WELFARE WORKER IN FACTORIES AND WORKSHOPS.

SIR,—The article entitled "The welfare worker in factories and workshops," in the issue of the BRITISH MEDICAL JOURNAL of January 28th, is both timely and important.

It is timely because at the present stage in the development of welfare work in factories and workshops the evils forecasted in the article are possible if proper advice is not forthcoming from the welfare worker when asked for as a result of collective discussion by workers and managers. As a specialist on employment questions, he is regarded as the official to secure for the workers what they in their committees desire. It would be a disaster if he advised or took part in procuring anything short of the highest medical opinion on questions of the establishment of works surgeries, or sug-

gested that the control be in any other hands than a qualified member of the medical profession. Members of the Welfare Workers' Institute have unfailingly insisted in the view outlined in the article.

It is an important contribution because it emphasizes the need for the closest co-operation through committees with the workers and the managers. Here again the Institute, ever since its inception in 1913, has taken the lead in establishing works committees as a medium for the closest co-operation on matters affecting the well-being of the workers.

May I be permitted to call attention to just one or two wrong impressions the article in question might convey to those who have not had actual experience?

It is suggested by inference that what may be learnt by the students in the university courses about health and hygiene might lead them to suppose they are fitted to carry out the principles in practice. Of course anyone with a knowledge of the courses would not make the error. As a matter of fact, what the student learns is that health is of first importance, and that it is of more importance that the charge of all health questions should be vested in members of the medical profession.

In another place it is suggested, also by inference, that there can be no place for a welfare worker in the scheme, since the experts are the proper people to be in charge of the specialist departments. It will, of course, always be necessary in modern factory administration to have one person whose special function it will be to see that all the regulations issued are being both understood and carried out in the works, and to bring to the notice of the experts those things with which they are specially concerned.

At the close of the article it is suggested similarly that the workers' committee can do what is done by welfare workers. Without a complete knowledge of the facts this statement might possibly be accepted by some readers, but of course, taken in the same spirit as the rest of the article, which insists on experts and specialists on expert and specialized work, it is hardly intended to mean that a member of the committee who might be, say, a bricklayer, should take over effectively the control of the engaging of labour for the rest of the factory or the administration of all the orders of the Government under Education Act, Factory Act, Health Insurance Act, etc., or regulations of trade agreements, when, after all, he is wholly or mainly required to lay bricks.—I am, etc.,

A. S. COLE,

Honorary Secretary, Welfare Workers' Institute.

11, Adam Street, Adelphi, W.C., Feb. 6th.

While recognizing the frankness with which Mr. A. S. Cole accepts the necessity for expert medical guidance in some matters connected with welfare work in factories, we do not think that his letter goes very far in allaying our apprehensions. Mr. Cole describes the welfare worker as a "specialist on employment questions," who will advise or take part in the establishment of works surgeries. We hinted a doubt whether the curriculum proposed by the Joint University Council for Social Studies would produce a specialist in anything; and we feel sure that the medical expert should advise the employer, and rather supervise than advise the welfare worker. We suggested that some of the work proposed to be done by the welfare worker could be handled by works committees, and mentioned more particularly thrift and recreation. Other portions of the work, such as the administration of orders under Education, Factory, and Insurance Acts seem to us to be matters for the employer, with such Government inspection as may be necessary. At the same time there can be no doubt of the usefulness of welfare workers, especially in connexion with the employment of women and girls. Our fear is that the proposed course of study of the Joint University Council may emphasize the idea of "specialism on employment questions," in the minds of welfare workers, whose activities, unless exercised with the utmost tact, may irritate both the management and the employed. The position of an official paid by the employer to secure for the workers what they in their committees desire would sorely be anomalous.

EXCHANGE OF CLINICAL INFORMATION.

SIR,—May I trespass on your space to draw attention to what appears to me to be a great defect in our hospitals?

It does not seem that hospitals make it an invariable rule to give any information to the general practitioner when a patient goes out of the institution. This is not to the advantage of the patient or calculated to assist in the further

treatment. Yet it is beyond doubt that everyone desires to obtain the best permanent results. Further, it is not courteous to either patient or general practitioner. I would suggest a brief form which could be filled in by the resident or the ward sister. It would simply state name, date of admission and discharge, diagnosis, treatment in brief, and treatment suggested in future. It would impress the patient with the care taken, and would often assist the general practitioner.—I am, etc.,

Market Lavington, Feb. 6th.

F. DE COVERLY VEALE.

X-RAY DEPARTMENTS.

SIR,—At a time when our hospitals, sanatoriums, child welfare centres and clinics represent such a substantial effort in the interests of the public health, I think it appropriate to suggest that there is one branch of work which might be developed, with benefit both to doctor and patient, along the lines of the public clinics, and that branch is radiography.

At present, as far as I understand, radiography is practised only in connexion with hospitals, except, of course, where patients can afford a specialist's fee. Thus, should a practitioner desire an x-ray photograph for diagnostic purposes, he must pass his patient through a hospital "out-patients" department, where the question of x-rays is subject to the decision of the medical officer. Were the practitioner to submit his patient with a request for radiographic examination for his personal edification, it would be regarded in the light of presumption, and would probably call forth the comment, "This is not a public x-ray department."

That is precisely the difficulty. I submit that there should be public x-ray departments, though I do not suggest that the hospitals should be called upon to do the work. The benefits from such departments would be twofold. First, a nearer approach to accuracy in diagnosis outside hospital, which would react directly and favourably upon the patient, and secondly, a new stimulus to a higher standard of work on the part of the general practitioner, which is seen to be an important consideration when it is remembered that the efficiency of the general practitioner is the efficiency of the medical profession.

Since he works at a disadvantage in being dobarred from the full clinical study of his cases in hospital, doubtless the practitioner would gladly grasp at the opportunity of having at his command the most modern and precise means of diagnosis.—I am, etc.,

Liverpool, Jan. 22nd.

C. H. ROSS CARMICHAEL.

THE NAVAL MEDICAL SERVICE.

SIR,—Ever since I left the navy in 1903 I have from time to time sent you letters which you have been good enough to publish. I am sorry to say that even now there is much well-justified discontent in the medical branch of the navy.

The root of the whole evil is the invidious distinction between the executive and civil departments. The Medical Director-General himself, on the broader questions, is allowed to be nothing but a figurehead—often very ornamental, but nothing more. And what can the best of good fellows do in such a position?

I wonder whether anyone remembers the case of Surgeon Lea (about 1890, before I joined the service), or Fleet Surgeon Charles Geikie Mathew (about 1904, after I had left it)?

This letter is not a criticism on the naval medical service, but it is questioning the attitude of the Admiralty towards their medical officers, and until there is a decided change in the methods of the authorities the medical profession will be well advised to give the Royal Navy a wide berth.

I venture to add a characteristic case. On the occasion of King Edward VII's coronation, medals were slapped about in Portsmouth and elsewhere among soldiers, sailors, and police; a considerable amount of extra and responsible work devolved on the staff of Haslar Hospital, but not a single medal was bestowed in that establishment. The present compulsory age retirement scheme is a very grave injustice to old and tried officers.—I am, etc.,

GERALD SICHEL

(Surgeon R.N. 1894-1903).

Sevenoaks, Feb. 2nd.

AN OLD MAN'S CHAIR.

SIR,—For some years I have induced many of my old and infirm patients to spend at least twelve hours a day sitting up in easy chairs. I mean such cases as asthmatics and heart

eases—even dropsical—with Southey's tubes or nicks in the skin to allow draining. I have tried many chairs, such as Chippendale and Hebblethwaite; all such chairs were too light and allowed slipping on the floor. There are many cases we cannot keep in bed.

We have become obsessed with the idea of a 3 ft. bed away from the wall, with spring mattress. I expect Hezekiah ordered his to be placed against the wall.

I have recently had made a chair at a cost of less than £2 which meets what I wanted. It is made of oak and is heavy; it weighs about 40 lb. The design is Chippendale, but with an upright back. It is roomy, with extended arms for resting; the arms are curved; the seat is flat, not hollowed out. This allows cushion for sitting if needed and the arms and back can have movable cushions according to wishes. There is no foot-piece.—I am, etc.,

Dulverton, Feb. 1st.

G. F. SYDENHAM.

EDUCATION AUTHORITIES AND THE SCHOOL MEDICAL SERVICE.

SIR,—The joint action to be taken by the British Medical Association and the Society of Medical Officers of Health in the matter of education authorities and school medical officers, referred to in your issue of January 21st, will be welcome to all doctors who have served directly (that is, who are not also medical officers of health) under education authorities as medical officers. Their position *vis à vis* the education secretary can be, and often is, humiliating. This is especially so when the individual in question, as is often the case with growing industrial towns in the North, is a man of little or no education beyond that acquired in the seventh standard and the secondary municipal school. Yet in all official matters the school medical officer is practically his subordinate. Circulars and communications from Whitehall directly affecting the medical officer and his department are addressed to him and have been known to get no further than his office. The visit of a medical officer of the Board is notified to him alone, and it is he who receives this officer on his arrival. It is within my own experience as school medical officer to have had no intimation of such a visit until the actual arrival of the official, although the visit had been notified to the education secretary a week previously. The annual report of the school medical officer passes to the secretary before being sent to the printer, and correction of (supposed) errors in English and orthography has not been unheard of. Sometimes, too, he may take a hand in the actual medical work in the schools. I can recall receiving a peremptory order through a clerk to visit a certain school regarding an outbreak of scarlet fever, of which as it happened I had already been notified in the usual way, through the head teacher.

I sincerely trust that the deputation will be able to make some impression on Sir Alfred Mond, and that the powers of some education secretaries will be suitably curtailed. I enclose my card.—I am, etc.,

February 8th.

IRATE S.M.O.

ALPINE TREATMENT OF TUBERCULOSIS.

SIR,—Sir Martin Conway, in his letter published under the above heading in your issue of February 11th, is mistaken in thinking that funds from the sale of the Queen Alexandra Sanatorium "are in the hands of its committee." The sale in question has not yet been carried out, nor has the council yet considered the question of the application of the proceeds. The closing of the sanatorium was not due, as might be inferred from his letter, to "an invasion of German lung cases during the war" at Davos. The sanatorium was closed owing to the difficulty of conveying civilian invalids through France to Switzerland, and of securing proper food and heating. After the war it was not reopened. This was by no means from any loss of confidence in the curative virtues of the Davos climate or in the value of our sanatorial treatment, but solely because the general rise in salaries and wages and in the cost of living, coupled with the adverse Swiss exchange, would have necessitated charging a much higher fee than could have been paid by the patients of small means for whose benefit subscriptions were originally raised and the sanatorium was built and equipped.—We are, etc.,

D. VESSEY,

WM. EWART, M.D.,

London, S.W., Feb. 13th.

Joint Honorary Secretaries, Q.A.S.

Universities and Colleges.

UNIVERSITY OF OXFORD.

Radcliffe Prize, 1922.—This prize, which is of the value of £50, will be awarded by the Master and Fellows of University College upon the report of the examiners, provided a sufficiently deserving memoir be submitted for adjudication, for a memoir, or papers, embodying research in any branch of medical science comprised under the following heads: Human Anatomy, Physiology, Pharmacology, Pathology, Medicine, Surgery, Obstetrics, Gynaecology, Forensic Medicine, Hygiene. The prize is open to all graduates of the University who have proceeded, or are proceeding, to a medical degree in the University. Candidates, at the date of application, shall not be Radcliffe Fellows; but the provision that candidates shall not have exceeded twelve years from the date of passing the last examination for the degree of B.A. is upon this occasion so far suspended as to enable any graduate, who was eligible during the years of the war (1915, 1917, 1919), to be eligible for the next ensuing award (1923).

Candidates are required to send their memoirs to the Assistant Registrar on or before Friday, December 1st, 1922. No memoir for which any University prize has been already awarded can be admitted to competition, nor may the prize be awarded more than once to the same candidate. Tuesday, March 20th, 1923, is the intended date of the award.

Romance Lecture.—The Romance Lecture, 1923, will be delivered by Arthur Stanley Eddington, M.A., Trinity College, Cambridge, F.R.S., Plumian Professor of Astronomy in the University of Cambridge, President of the Royal Astronomical Society, on Wednesday, May 23rd, at 6 p.m., on the following subject: The Theory of Relativity and its Influence on Scientific Thought.

Degree Days.—Congregations will be held for the purpose of conferring degrees on the following days at 2.30 p.m.: Saturday, Feb. 18th, Thursday, March 9th, Saturday, April 8th.

UNIVERSITY OF CAMBRIDGE.

PROFESSOR J. T. WILSON, M.B., F.R.S., has been appointed a member of the Managing Committee for the diploma in Psychological Medicine, and Dr. W. L. Dixon, F.R.S., a member of the Committee on Medical Radiology and Electrology, both in the place of the late Professor Sir G. Sims Woodhead.

Mr. Walwyn Thomas, M.B., resident at Capetown, has been approved for the degree of M.D. in absence.

At a congregation held on February 11th the following medical degrees were conferred:

M.B., B.Ch.—D. D. Evans, A. T. Hawley.

M.B.—C. F. McFadyen.

B.Ch.—R. S. Corbett, G. I. F. Tweedie, P. D. H. Chapman.

* Admitted by proxy.

UNIVERSITY OF LONDON.

A MEETING of the Senate was held on January 25th. The Vice-Chancellor announced that he had accepted an invitation from the University Unionist Association to become a candidate for the representation of the University at the next general parliamentary election, and that as the Vice-Chancellor is the returning officer for that constituency it would be necessary for him, should a general election be decided upon before the expiration of his term of office, to resign that office as soon as such decision was pronounced. It was decided to designate the Principal Officer to act temporarily as returning officer in the event of a vacancy in that office.

Professor A. D. Waller, F.R.S., and Dr. T. D. Lister were re-elected Director and Treasurer respectively of the Physiological Laboratory until the end of the session 1921-22.

The regulations for the intermediate examination in science for internal students were amended whereby students who have passed the second examination for medical degrees (Part II) will be exempted from examination in physiology at the intermediate examination in science.

Sir William Collins was appointed the representative of the University at the Royal Sanitary Institute Congress to be held at Bournemouth in July. The Vice-Chancellor (Sir Sydney Russell-Wells) was appointed one of the University delegates at the Congress of Universities of the British Empire to be held in London in May.

Applications for the chair of physiology tenable at St. Bartholomew's Hospital Medical College with salary of £1,000 a year, and for the chair of surgery tenable at St. Mary's Hospital Medical College with salary of £2,000 a year, should be sent not later than February 24th.

University medals at the M.D. examination for internal and external students, December, 1921, have been awarded as follows: Branch I (Medicine) to Laurence Ball (University of Birmingham); Branch IV (Midwifery and Diseases of Women) to Janet McAllister McGill (London R.F.H. School of Medicine for Women); Branch VI (Tropical Medicine) to Charles T. Maitland (St. Bartholomew's Hospital and London School of Tropical Medicine).

A Carpenter Medal, together with a money prize of £25 in all, will be awarded for a thesis of exceptional distinction in statistical, genetic, comparative or experimental psychology, including the functions of the central nervous system and special senses for which a doctor's degree has been awarded during the three years ending May 31st, 1922.

Applications for grants from the Dixon Fund for the purpose of assisting scientific investigations should be sent in between April 1st and May 15th.

The Lindley Studentship, value £120, will be awarded to a student qualified to undertake research in physiology in the Physiological Laboratory of the University. A statement of qualifications and mode proposed to carry out research must be forwarded to the Academic Registrar by May 1st, from whom further particulars can be obtained.

A University Studentship in Physiology, value £50 for one year, to undertake research in physiology in the Physiological Laboratory of the University or of a school of the University, will be awarded. Applications to the Principal Officer by May 31st, from whom full particulars can be obtained.

A course of four lectures on some recent developments in pharmacology will be given by Dr. H. H. Dale, F.R.S., at the Lanyon (R.F.H.) School of Medicine for Women, on Wednesdays, February 22nd, March 1st, 8th, and 15th, 1922, at 5 p.m.

The Chairman of Convocation announced his intention not to seek re-election at the expiration of his present term of office. On the motion of the Vice-Chancellor, seconded by Dr. Walsley, a unanimous vote of thanks was accorded to Sir Edward Busk for his great services to the University and Convocation during his long term of office.

UNIVERSITY OF SHEFFIELD.

The following appointments have been made:—Lecturer in Pharmacology: H. W. Scutgate, M.B., B.S., B.Sc. Assistant Curators of the Pathological Museum: E. F. Finch, M.D., M.S., F.R.C.S., and V. Townrow, M.B., B.S., F.R.C.S. Demonstrator in Medical Pathology: A. G. Yates, M.D., M.R.C.P.

The following candidates have been approved at the examinations indicated:

FINAL M.B., Ch.B.—H. Finklestone, Mary P. Gell.
D.P.H.—Dorothy E. Mathews, J. Rennie.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

AN Ordinary Council was held on February 9th, when Sir Anthony Bourlby, President, was in the chair.

Diplomas were issued to ninety-one candidates found qualified for the Membership of the College. Diplomas were granted, conjointly with the College of Physicians, to eleven candidates in Ophthalmic Medicine and Surgery.

Mr. W. G. Spencer was appointed Vicary lecturer, and Sir William Thorburn was appointed Bradshaw lecturer.

Mr. Raymond Johnson was re-elected a member of the Court of Examiners. Dr. W. S. A. Griffith was re-elected a representative of the College on the Central Midwives Board. Mr. H. J. Waring was appointed as the College representative on the General Medical Council for five years.

Mr. Clement E. Shattock was appointed Pathological Assistant.

Diploma of Ophthalmic Medicine and Surgery.—The vacancy occasioned by the resignation of Mr. E. Treacher Collins will be advertised on April 8th next, with the other examinations becoming vacant, and will be filled up at the annual election of examiners on June 8th. Mr. J. H. Fisher and Sir William Thorburn were appointed to conduct the special examination in Ophthalmology for Fellows during the ensuing nine months. [The examinations are held in June and December.]

Council Election.—The President reported that a meeting of the Fellows would be held at the College on Thursday, July 6th, for the election of three Fellows into the Council in the vacancies occasioned by the retirement in rotation of Sir Charles A. Ballance, Sir William Thorburn, and Mr. W. McAdam Eccles; that notice of the meeting would be given to the Fellows by advertisement and by circular on March 15th, that March 20th would be the last day for the nomination of candidates, and that a voting paper would be sent on April 4th to every Fellow of the College whose address is registered at the College.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS.
GLASGOW.

THE following have, after examination, been admitted Fellows of Faculty: Matthew White, Purnanada Roy.

Obituary.

WE regret to record the death, in his 74th year, of Dr. EDWARD SERGEANT, who was medical officer of health for Lancashire from 1890 to 1917. Educated at St. Thomas's Hospital, he qualified with the diploma of M.R.C.S. Eng., L.R.C.P. Lond., and L.S.A. in 1871; he further obtained the public health qualification of L.S.Sc. Durham in 1893. In the Franco-Prussian war he served as assistant surgeon at Bingen, on the Rhine, and organized hospitals at Zorbach, Metz, and Strasbourg. After holding the post of senior house-surgeon at Bolton Infirmary he was, in 1874, appointed medical officer and public analyst to the borough of Bolton. He was appointed to the post of medical officer of health for Lancashire, with headquarters at Preston, in 1893. Dr. Sergeant contributed a number of articles to the medical journals on public health administration. He was an old member of the British Medical Association, and a former president of the Society of Medical Officers of Health.

We regret to announce the death of Dr. ANDREW ROSS LAING, which took place at Aberdeen on January 26th. Born in that city just over fifty years ago, Dr. Laing graduated M.B., C.M. at Aberdeen University in 1897, and took the diploma in public health in 1899; he graduated M.D. in 1905. He served as a civil surgeon with the field forces in South Africa in 1899-1900, but for health reasons he had to return home, and in 1901 was appointed assistant in pathology at Aberdeen University. Subsequently he held the posts of city bacteriologist and lecturer on hygiene at Aberdeen Training College, and he was medical officer to Aberdeen Dispensary. He published several articles, chiefly connected with the subject of public health. Dr. Laing had an extensive private practice in Aberdeen, and with his skill as a physician he combined a sympathetic personality which endeared him to his patients. In his university days he was prominent at games, and latterly he was in the front rank of local amateur golfers. He leaves a widow and two young children.

The death is announced of Dr. JOSEPH MACDONALD of East Orange, New Jersey, who founded in 1905 the *American Journal of Surgery*, of which he was managing editor. He was for many years secretary of the American Medical Editors' Association, and served for one term as its president. During the war he was a major in the United States Army Medical Corps.

PROFESSOR GIACOMO CIAMICIAN, a distinguished Italian chemist and former Nobel prizeman, has recently died.

The Services.

NAVAL MEDICAL COMPASSIONATE FUND.

A MEETING of subscribers of the Naval Medical Compassionate Fund will be held at the Medical Department of the Navy, 38, Victoria Street, S.W., on April 11th, at 11.30 a.m., to elect six directors of the fund.

DEATHS IN THE SERVICES.

MAJOR-GENERAL WILLIAM HENRY BANNER ROBINSON, C.B. Bengal Medical Service, died in Calcutta on February 7th, aged 58. He was the son of Commander Charles Aylmer Robinson, R.N., of Kingstown, and was educated at the Carmichael School and Meath Hospital, Dublin, taking the L.K.C.S.I. in 1883 and the L.K.Q.C.P. in 1884. He took the D.P.H. of the Irish Colleges in 1893. Entering the I.M.S. as surgeon on April 1st, 1885, he attained the rank of colonel on December 1st, 1915, and was promoted to surgeon-general on January 8th, 1918, becoming major-general when this title was granted to the medical services in the same year. He served for four years in the Burma campaign, 1885-89 (mentioned in dispatches, medal with clasp), and in three campaigns on the North-West Frontier of India—Waziristan, 1894-95 (clasp); Chitral, 1895, relief of Chitral (medal with clasp); Tirah, 1897-98; operations in the Bara Valley (clasp). In 1902 he entered political employment as agency surgeon of the State of Bikanir, and in 1910 became residency surgeon, Mount Abu, and principal medical officer of Rajputana. In September, 1914, he returned to military duty, and served for two years in Egypt as principal medical officer of the Indian troops there. He was twice mentioned in dispatches, in the *London Gazette*, and received the medal, 1914-15 star, and victory star, as well as the C.B. On his return to India he was appointed inspector-general of hospitals in the Central Provinces, and in March, 1918, surgeon-general of Bengal and member of the Bengal Legislative Council. Last year he acted for six months as director-general of the I.M.S. during the absence on leave of Sir William Edwards, and at the time of his death was on the eve of retirement, after nearly thirty-six years' service. He received the second class of the Kaiser-i-Hind Order in 1901, the Knight's Cross, first class, of the Order of Philip the Magnanimous of Hesse in 1904, and on April 22nd, 1919, was appointed an honorary surgeon to the King. He married Elsie Marian, daughter of the late Dr. William Deane Butcher, of Ealing, and leaves a family.

BREVET-COLONEL SIR JOHN GODFREY ROGERS, R.A.M.C.(ret.), died at Edenbridge, Kent, on January 10th. He was born on April 11th, 1850, and educated at Trinity College, Dublin, where he graduated B.A., M.B., and M.Ch. in 1871. He entered the army as assistant surgeon on September 30th, 1871, became surgeon-major on April 18th, 1882, getting a special promotion for service in the Egyptian war, and surgeon lieutenant-colonel on April 1st, 1891. He retired on February 3rd, 1892. In the old regimental days he served in the 67th Foot (Hampshire Regiment). On November 1st, 1883, he was seconded for service with the Egyptian army and served as Principal Medical Officer of that force till he retired from the British army in 1892. He still remained in the Egyptian service as Director-General of the Sanitary Department in that country, holding that post for eight years, till 1900. He had a very long list of war service, as follows: Afghanistan, 1878-80, with Kandahar Column and Ghazni Field Force, medal; Egypt, 1882, with the 19th Hussars, actions of Kassassin and Tel-el-Kebir, mentioned in dispatches, medal with clasp, Khedive's bronze star, and special promotion to surgeon-major; Sudan, 1884-5, with Nile

Column, as P.M.O. Egyptian troops, mentioned in dispatches, clasp; Sudan, 1885-8, action at Ginniss, mentioned in dispatches, D.S.O.; Suakin, action of Gamaizah, mentioned in dispatches, *London Gazette*, January 11th, 1889, clasp, and 2nd Class Medjidie. In the late war he served as British Commissioner of the Red Cross in Cairo in 1915-8, and was mentioned in dispatches in the *London Gazette* of June 21st, 1916, and January 12th, 1918. He received the Osmanieh, 3rd Class, in 1885, and 2nd Class in 1901; the D.S.O. in 1887; the Medjidie, 2nd Class, in 1890, and 1st Class in 1901; the C.M.G. in 1896; the K.C.M.G. in 1898; the 2nd Class of the Order of the Nile in 1918, knighthood of St. John of Jerusalem in 1918; and a brevet colonelcy on January 1st, 1919; and had the title of Pasha in Egypt. In 1912 he published a book called *Sport in Fancourt and Newfoundland*. In 1883 he married the daughter of Major Sykes, Bombay Cavalry; she has received the C.B.E. and is a Lady of Grace of the Order of St. John of Jerusalem.

Medical News.

THE death rate for the city of New York during 1921 was the lowest ever recorded by the Health Department. The death rate in 1921 was 11.17 per 1,000 of the population, as compared with 12.93 in 1920. In Chicago the death rate was even lower than in New York, being just under 11 per 1,000 of the population. These figures are slightly better than those for this country. The crude death rate for London in 1921 was 12.4; in the 95 great towns, with populations exceeding 50,000, it was 12.3; in 148 smaller towns it was 11.3; the rate for the whole of England and Wales was 12.1.

It is stated that in Berlin the manufacturers of x-ray apparatus have offered to finance an institution for training in x-ray work, containing laboratories and lecture rooms, but not intended for research. The university authorities protested against the idea of a private institution of this kind, and suggested instead that it should be organized as a university institute, or that the manufacturers should endow the institutes already organized in this department; the Kaiser Wilhelm-Forschungs Institut, for instance, was endowed by the organized manufacturers.

THE 195th dinner of the Edinburgh University Club of London took place at the Connaught Rooms on February 8th, with Sir Henry Craik, K.C.B., M.P., in the chair. Among those present were Lord Aberconway, Sir George Andreas Berry, Dr. A. Blackball-Morison, Dr. George C. Cathcart, Mr. C. C. Choyce, Sir James Crichton-Browne, Sir Dyce Dnekworth, Sir James Dundas-Grant, Dr. J. T. C. Laing, Sir Duncan J. Macpherson, Major-General Sir W. G. Macpherson, Dr. H. Crichton Miller, Dr. Nathan Raw, M.P., Sir Charles Ryall, Sir George A. Touche, Sir John Thomson Walker, and Dr. S. A. Kinnier Wilson. After the loyal toasts had been honoured, Sir Henry Craik proposed the toast of "The Alma Mater and the Edinburgh University Club in London," giving an account of the effects of recent legislation upon education in Scotland, and emphasizing the harm that the so-called democratization of university education would do. He did not believe that evening classes in the Scottish universities, as had actually been proposed, were a suitable form for the extension of university education: he believed rather in the intensive type of university study which at present existed. The health of the Chairman was proposed by Sir George Andreas Berry, in a witty speech, enlivened by characteristic Scottish anecdotes. Membership of the Edinburgh University Club of London, which dines thrice in a year, is open to all members of the university, and further particulars may be had from the honorary secretary, Dr. R. S. Frew, 73, Wimpole Street, W.1.

THE United States board of directors of the Gorgas Memorial Institute has elected Dr. William C. Braisted president, Dr. Arthur P. Robbins executive secretary, and Mr. Edward J. Stellwagen treasurer. The purpose of the organization of an executive committee in the United States is to further the movement to introduce the sanitary methods devised by the late Surgeon-General Gorgas into all the civilized countries of the world. It was announced recently that Dr. Richard P. Strong, dean of the department of tropical medicine at Harvard University, and formerly director of the biological laboratory at Manila, had accepted the post of scientific director of the Gorgas Memorial Institute of Tropical and Preventive Medicine. This institute is to be built at Panama City on a site presented by Dr. Belisario Porras, President of the Republic of Panama, and the Panama Government has also provided a building and modern equipment to the value of half a million dollars, as well as the use of the important Santo Tomas Hospital, which is on the point of completion.

MME. GEORGES DIEULAFOY, the widow of the late Professor Dieulafoy, has presented to the Paris Faculty of Medicine an annual sum of Fr. 26,000, to be distributed as follows: Fr. 8,000 to the medical clinic of the Hôtel-Dieu, of which her husband

and Trounseau were the chiefs: Fr. 8,000 to Professor Vidal's clinic at the Hôpital Cochin, Fr. 5,000 to Professor Chaurand's clinic at the Hôpital St. Antoine, and Fr. 5,000 to the chair of pathology occupied by Professor Rénou.

At a sessional meeting of the Royal Sanitary Institute to be held at the Town Hall, Leeds, on February 24th and 25th, at 7 p.m., a discussion on the limitations of bacteriology in connexion with public health work will be opened by Dr. J. W. McLeod, lecturer in bacteriology in the University of Leeds. Dr. A. E. Pearson, medical superintendent of the Seacroft Infectious Diseases Hospital, will open a discussion on hospital management and treatment of infectious diseases.

THE joint convancers of the Historic Monuments Committee of the St. Andrew Society, Glasgow, have addressed a letter to the *Glasgow Herald* supporting the appeal of Professor Robert Kennedy for the preservation of Lister's ward at the Glasgow Royal Infirmary. They appeal very strongly to the Board of Management of the Infirmary to rescind its decision to abolish the ward, the removal of which, they assert, would be a wanton piece of vandalism.

THE eighty-sixth annual meeting of St. Mark's Hospital for Cancer, Fistula and Other Diseases of the Rectum was held at the Mansion House on February 9th. The Lord Mayor, who presided, commended the good work accomplished by the hospital, and expressed the hope that in spite of the great difficulties of the times the necessary income would be forthcoming. It was stated that the purchase of the adjoining site had been completed, and that the sum of £10,000 was needed to build an extension which was much needed.

DR. JOHN GILMOIR, late of Dalnair, has been made the recipient of handsome gifts from his friends and admirers in the district in connexion with his appointment by the Scottish Board of Health to be a junior district officer for the south-western district of Scotland, with headquarters in Glasgow.

OWING to the frequency of complaints of the dearth of gynaecological teaching and experience for post-graduates in London, the staff of the Hospital for Women, Soho Square, has organized a definite scheme to meet the demand. Three sessions a year are held in January, March, and October, each of six weeks' duration, where the post-graduates have daily opportunities of gaining experience in this subject. The hospital is well adapted for the purpose, being a modern building with 63 beds and 14,000 out-patients a year. It has a laboratory and museum and an installation of the latest x-ray plant for the treatment of carcinoma of the uterus. Particulars of the next session, which commences on Monday, March 13th, appear in the advertisement columns, or information may be obtained from the Dean at the hospital.

UNDER the auspices of the Blackburn and District Medical Society a dinner was held on February 2nd, at Blackburn, with Dr. F. W. Taylor, president, in the chair. The Mayor of Blackburn proposed the toast of the newly-revived Blackburn and District Medical Society. Speaking as chairman of the Health Committee and of its daughter-committee, the Publicity Committee on Health, he declared that one of the most important factors in determining the success or otherwise of any scheme of preventive medicine was the attitude towards it of the medical profession. The private practitioner was in the van in the fight against disease, and he knew that the Health Committee—six of whose number in Blackburn were members of the medical profession—and their medical officer of health, were most anxious to secure their co-operation. Dr. F. W. Taylor, in reply, said that the Medical Society was an old organization which had showed ready adaptability to the changed conditions which time had brought about. He welcomed the resuscitation of the activities of the society, and hoped it would ultimately furnish some sort of post-graduate instruction for the practitioners in the district. The toast of "The Guests" was proposed by Dr. J. T. T. Ramsay, and responded to by the Town Clerk of Blackburn. The health of the President was proposed by Mr. L. King-Wilkinson, and in responding Dr. Taylor expressed the thanks of the gathering to Dr. Ramsay and Dr. Shaw, who had organized it.

THE number of deaths from influenza in the week ending February 11th shows a very appreciable decrease, being 759 in the 105 great towns, and 749 in the 96 great towns of England and Wales, as against 1,144 and 1,121 in the week ending February 4th, a decrease of 34 and 33 per cent. respectively. The figures are the lowest recorded in the present year. In London the deaths numbered 109 against 191 in the previous week, a decrease of 43 per cent. There were slight increases in Birmingham (52 against 46), Liverpool (45 against 38), and Cardiff (27 against 26). In Edinburgh and Glasgow the deaths from influenza numbered 48 each against 99 and 150 respectively.

At the next meeting of the Medico-Psychological Association of Great Britain and Ireland, to be held at 11, Chancery Street, Cavendish Square, W., on Thursday, February 23rd, at 2.45 p.m., Dr. T. S. Good will read a paper on "The Use of Analysis in Diagnosis." The chair will be taken by the President, Dr. C. Hubert Bond.

At the Liverpool Assizes, on February 7th, Dr. H. E. Annett brought an action for damages for wrongful dismissal against Messrs. Evans, Sons, Lescher and Webb, Ltd., wholesale chemists in Liverpool. From the opening statement by counsel for the plaintiff, as reported in the *Liverpool Daily Courier*, it appeared that Dr. Annett, who was formerly Professor of Pathology in the University of Liverpool, became superintendent of a laboratory established by the defendants at Runcorn in 1911 for the manufacture of what is known as the Liverpool virus. In the early days the royalties received by Dr. Annett amounted to about £300 a year; during the last year or two the sales had amounted to from £15,000 to £20,000 a year. Last May a foreman of the laboratory pleaded guilty to misappropriation of funds and was fined £50. On the following day a member of the defendant firm wrote to Dr. Annett summarily dismissing him. Counsel for the defendants said there was no reflection on Dr. Annett's integrity, but the defendants could not be expected to have further confidence in him after this incident. The judge held that the defendants were not entitled to dismiss Dr. Annett summarily, and gave judgement for six months' salary (£225) with costs.

IN consequence of the number of persons who discontinue treatment while still in an infective condition, the National Council for Combating Venereal Diseases has passed a resolution urging the Government to consider what further steps can be taken to secure the adequate prevention and treatment of venereal diseases, and requesting that efforts should be made to secure the continuous treatment of infective persons.

THE Order of the Nile (fourth class) has been conferred upon Dr. Henry C. Squires, senior medical inspector of the Sudan Government, in recognition of valuable services rendered.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Attorney*, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Malvern*, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 17, Frederick Street, Dublin. Telegrams: 7, Dublin; and of the Scottish Office, (Telegrams, Associate, Edinburgh).

QUERIES AND ANSWERS.

INCOME TAX.

"S. C." was resident abroad until October 15th, 1921, and commenced practice on January 15th, 1921. He inquires what is his liability.

"We assume that he has not come to this country for a temporary purpose only. He is liable to assessment in respect of the period to April 5th, 1921, and for the year ending April 5th, 1922. The ordinary method of computing the liability in respect of the earnings would be to prepare, in due course, a statement of receipts and payments for the eleven and a half months to December 31st, 1921. Of the result shown 2 1/2% would represent the 1920-21 liability and 12 1/2% the 1921-22 liability.

"MDAS" inquires whether deductions can be claimed in respect of payments of bank interest.

"Yes; in the case to which he refers the loan was a private one. Bank interest is an exception to the statutory rule."

THERAPEUTIC USES OF ANTIMONY.

Dr. F. G. CAWSTON (Durham, Natal) writes: I notice that extracts from papers of mine and private communications on the subject of antimony in treatment are being published without my knowledge or consent. I have never intended them to be used in a commercial way and hope that they may still be taken merely as preliminary reports for the benefit of those who are less handicapped than myself and are better able to follow up these investigations on a more extensive scale.

LETTERS, NOTES, ETC.

SCARLATINA-LIKE RASH IN INFLUENZA.

Dr. BERNARD E. POTTER (London, W.) writes: The note by Dr. Edgar F. Cyriax of the occurrence of initial symptoms of scarlet fever in what proved later to be a case of influenza reminds me of a similar case in April, 1914, which occasioned more than the usual trouble and anxiety associated with the diagnosis of scarlet fever. The temperature was 102° and the rash over the body resembled that of scarlet fever and mild throat signs. Being in some doubt, as there was history of a similar attack with subsequent desquamation, a fever specialist was called in, who diagnosed scarlet fever, and the medical officer of health was duly notified. Later, however, Dr. W. H. White, who had seen the patient before, was summoned, and he diagnosed influenza without the slightest hesitation, as this condition was well known to him. The notification was cancelled. Peeling followed soon afterwards, but it was clearly evident that influenza was the cause, the more so as the same kind of illness had happened within the year.

ELECTRO-VIBRATION OF THE CEREBELLUM AND PANCREAS IN DIABETES MELLITUS.

Dr. ERNEST KINGSCOTE (London, W.) writes: Dr. Baumann ends his instructive article on "The modern dietetic treatment in diabetes mellitus" (BRITISH MEDICAL JOURNAL, December 17th, 1921, p. 1027) in the following words: "Some day we may hope to be able to stimulate or strengthen the pancreatic function in a direct manner, and so to supersede palliative measures by actual cure." I suggest that possibly we have such a means to hand in electro-vibration. This is purely mechanical in its action. The vibrator is driven by the electric current through a wall plug and there is no transmission of the electric fluid to the patient. Such vibration is very far-reaching in its effects and stimulates deep-seated organs and shakes out congestions and accumulations of fluid. Between 1906 and 1910 20 cases of diabetes mellitus were treated centrally by vibration of the fourth ventricles and locally over the pancreas, the tenderness of which was much relieved thereby. The central vibration was not unpleasant to the patients and the frequent headaches were much relieved. In every case the sugar output was diminished without altering the diet. Of these 20 cases 16 are now alive and well and free from saccharosuria; the blood sugar was not estimated. A feature common to all of these cases was fixed upper chest with eversion of the free ribs and abdominal protuberance, thus reducing lung suction and hampering the circulation of the brain and abdominal organs. This condition was treated by the Kingscote Breathing Exercises for the reproduction of chest movement in emphysema, etc. (demonstrated before the Medical Society of London in November, 1921). In 1906 a boy, aged 17, was sent home from Harrow School because it was said that he had been overworking and required rest. He was naturally a brilliant lad, but had become listless and suffered from headaches. The urine was found to contain 5 per cent. of sugar and traces of acetone and diacetic acid. There was tenderness on deep pressure over the pancreas, and the body weight was reduced. The chest excursion was only half an inch. The central vibration was administered through the medium of an air-cushion vibratode daily at first for five minutes a session, but increased to ten minutes on finding that the treatment was well tolerated. After six weeks the sugar output was reduced to 1 per cent. and acetone and diacetic acid were absent. In three months there was no more sugar excreted. The patient now began to put on weight and the polyuria became insignificant. Fifteen years afterwards he tells me that he has had no more trouble, and that he is now on the staff of a leading London journal. This line of treatment was successful with 16 out of 20 of these cases. Why it failed with the other four I do not know.

STARTING A MOTOR IN COLD WEATHER.

VIATOR? writes: With due respect to your valued contributor, Mr. Buist, I cannot see any reason either to purchase aviation spirit or dismantle one's carburettor to get a quick start in cold weather. A rubber water-bottle filled with very hot water and wrapped round the carburettor and induction pipe for a few minutes before starting up will do the trick. Also in those engines whose cylinders are provided with compression taps a few drops of a mixture of equal parts of ether and petrol run through these taps are almost a specific. My experience, after eighteen years of being my own chauffeur, leads me to the opinion that in 90 per cent. of jibbers the fault is the carburettor and not the petrol. My Overland no matter how cold the weather never fails to start at the first pull when I have turned the cranking handle quietly round four times to get some juice into the engine. My Ford is almost as tractable, and in these cars the proper mixture for starting and running can be obtained in less time than it takes to talk about it—a great treat after years of jibbing carburettors—most of them badly designed and incapable of any but the crudest regulation.

MEDICAL EXAMINATION OF EMPLOYEES.

THE Medical Committee of the Industrial Welfare Society is, at the request of manufacturing firms, engaged in drawing up a form for the use of medical officers when examining employees. The chairman of the committee, Dr. C. A. Coles, desires to enlist the co-operation of managers and medical officers; forms now in use, or suggestions which will be of assistance in compiling a model form, may be sent to him at the Industrial Welfare Society, 51, Palace Street, Westminster, S.W.1.

THE ROTARIAN IDEAL AND THE MEDICAL PROFESSION.

Dr. G. NORMAN MEAGHERY (Southend-on-Sea) writes: During the past few years a considerable number of medical men have allowed themselves to become enrolled as members of the local Rotary Club, should one happen to exist in their neighbourhood. Apart from the medical instinct which impels the practitioner to cultivate an acquaintance with every new movement established for the social betterment of the race, there is much in common between medicine and rotary. In the first place, both are pledged to the service of humanity and both are agreed that the setting aside of their own interests in favour of those of others constitutes the highest law. The rotarian motto, "Service above Self," has, indeed, been characteristic of medical practice from time immemorial, both consciously and unconsciously, and it embodies the noblest traditions of the healing art. It is not surprising, therefore, that medical men should not only find themselves drawn into rotary, but that they should in the very nature of things play a not unimportant part in its proceedings.

There is nothing new in rotary except its organization, and, as Rotarian James Dalzell of Belfast points out in the current issue of the *Rotary Wheel*, it is doubtful "if Paul Harris and his four friends when they met in turn sixteen years ago, and organized the first Rotary Club, had any clear conception or intention that Rotary should eventually evolve into the peculiar movement it now is."

As a non-political, unsectarian society, existing for the avowed object of fostering the highest business and professional ideals, and of promoting the best moral and social interests of the community, it is bound not only to enlist the sympathy but also to command the active support of every medical practitioner. On the one hand, the club benefits from the doctor's special experience and advice upon various social topics, and on the other, he himself will gain in breadth of outlook and in increased knowledge of other activities than his own purely professional ones. The practitioner's sphere of usefulness must tend, through his association with rotary, to develop, and as there are committees to deal with various activities, there will be ample opportunity for the medical man to make his influence felt in the cause of health and right living. The subject of boy welfare is one which is being warmly taken up by many rotary clubs, and this development, fraught with immense possibilities for good, is closely associated with the whole movement of child welfare and with the physical improvement of the parents of the next generation. The medical man's sympathy and co-operation in this and kindred branches of rotarian activity cannot fail to be of much help at the present time.

The similarity between the aims of Rotary and those of Freemasonry has been pointed out. It is true that the two societies are each founded upon the purest principles of brotherly love and service, but the former is simpler and less restrictive than the latter, and, of course, it possesses neither the antiquity nor the special privileges which are the peculiar property of the latter. Nevertheless, rotary makes a prompt and a widespread appeal to the hearts of men who are and who are not members of the older fraternity, and medical men are bound not only to be influenced themselves by its spirit but also to accord to the "new freemasonry" their active interest and hearty support.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 28, 29, 32, and 33 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 30 and 31.

THE following vacant appointments of certifying factory surgeons are announced: Dalkeith (Edinburgh), Hungerford (Berks), Woking (Surrey).

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	0 9 0
Each additional line	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 15 0
Half page	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *poste restante* letters addressed either in initials or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

150. Cephalic Bruits in Children.

FRILL (*Brit. Journ. Child. Dis.*, October-December, 1921) describes a condition which has received little attention in most recent textbooks on children's diseases, partly because the bruits have no recognized pathological significance, and partly because they have been supposed to possess no clinical interest. These bruits were first described by Fisher of Boston in 1833 and later by Whitney in 1846, both of these writers regarding the bruits as of pathological significance and indicative of some organic affection of the brain. Osler, who recorded a case in an otherwise healthy child in 1880, pointed out that the extreme ages at which the murmur prevailed were the third month and the sixth year, the majority occurring in the second year. His own case was exceptional in that the bruit was still present at the age of seven years. Subsequent observers found that the bruit was so frequently audible in children during the first three years of life that its pathological significance was open to doubt. Still, who has examined 200 children for the presence of the bruit, has found it in 13 out of 130 with the fontanelle closed and in 17 out of 70 with the fontanelle open. The youngest case in which it was heard was aged six months and the oldest fifteen years, but no patient beyond that age was examined. Only four cases were met with above the age of four years. Still was unable to connect the bruit with any particular morbid condition, all sorts of diseases being present in the thirty cases in which it was detected, including scurvy, epilepsy, achondroplasia, nephritis, asthma, congenital syphilis, congenital heart disease, acidosis, and dyspepsia while four had nothing at all. Still thinks that tortuosity at the base of the skull is a factor in the production of the murmur, and that some straightening of the course of the artery occurs with increase in the size of the skull. He suggests that persistence of the bruit beyond the usual age is due to unusual thickness of the bony wall of the carotid. The bruit has a systolic blowing, sometimes almost twanging character, which is very different from the continuous hum of the venous bruit.

151. Treatment of Whooping-cough.

HALPHEN (*Rev. de l'ar. d'otol., et de rhin.*, December 15th, 1921) has treated several cases of whooping-cough, of which he reports five examples in children, aged from 4 to 6 years, by producing anaesthesia of the superior laryngeal nerve, irritation of which he maintains is the chief cause of all spasmodic coughs. The technique is as follows: The greater cornu of the hyoid above and the thyroid cartilage below being taken as landmarks, the needle of the hypodermic syringe is thrust in midway between these two points, at first superficially and parallel with the skin, and then perpendicularly to it below the thyro-hyoid muscle, to the depth of about 1 cm.; 2 to 3 c.cm. of alcohol (90 per cent.) are then injected on each side. It is important that the alcohol should be cold, for when heated it has an anaesthetic effect, and it is necessary for the patient to complain of a pain radiating to the ear to make sure that the needle is in contact with the nerve. In pertussis this is shown by an immediate outbreak of an extremely violent and typical attack of whooping. During the next two or three days the paroxysms diminish in frequency and intensity, completely ceasing on the fourth or fifth day, although the cough does not cease entirely. The child seems to be husky for a few days, but at the end of a week he is quite cured. In some children a single injection is sufficient, but in others two are required. In a few cases the treatment was unsuccessful, although several injections were given.

152. Tubercular Leprosy.

ARCHIBALD (*Journ. Trop. Med. and Hygiene*, November 1st, 1921) records a case of tubercular leprosy treated by intravenous injections of antimony in the shape of stibényl, the sodium salt of p-acetylaminophenylstibinic acid. In a previous case treated intravenously with colloidal antimony sulphide (1.5 grain) the lesion had almost disappeared and the lepra bacilli showed marked degeneration after ten injections, after which the patient was lost sight of. The case recorded was a Sudanese, aged 40, with lepromatous nodules on the face, nose, trunk, tongue and larynx. Smears from the nasal mucus showed lepra bacilli. A 1 per cent. normal saline solution of the salt was employed in dosages of 0.1, 0.15, 0.2, 0.4, 0.5, and 0.6 gram given intravenously on alternate days, the

course being repeated after an interval of ten days' rest. Considerable improvement resulted, the lepromata, nasal ulceration, and leonine facial appearance having practically disappeared by the end of the fourth course, after a total administration of 7.8 grams. Smears from the nasal mucus and nodules showed degenerated coecal forms of bacilli lying free and intracellularly with a few very granular bacillary forms. Beyond slight nausea and diarrhoea there were no ill effects, and a slight albuminuria was not a contra-indication to the treatment. The result surpassed any obtained by the use of sodium glycinate, and a more intensive treatment with stibényl is suggested.

153. Diagnosis of General Paralysis.

ACCORDING TO TARGOWLA (*Ann. de Med.*, October, 1921), lymphocytosis in general paralysis, though of great diagnostic value, does not give any information as to the intensity of the meningo-encephalitis. The Wassermann reaction, although the reaction may be persistently negative during a remission. High tension of the cerebro-spinal fluid is in favour of an intense meningo-encephalitis, but there are frequent exceptions. The amount of albumin in the fluid varies too much to have any clinical significance. When it is normal the disease may be regarded as more or less inactive. An abnormal quantity of urea (40 eg. or more), independently of any sign of Bright's disease, is found whenever there are any superadded signs of toxic origin, and often coincides with a well marked benzoin reaction. Pandy's reaction is more definite and, with some exceptions, bears a direct relation to the intensity of the disease. The colloidal benzoin reaction, apart from its diagnostic importance, is a valuable guide as to the intensity of the meningo-encephalitis. In association with the clinical signs it possesses considerable prognostic value and is also a guide to treatment.

154. Strauss's Water Test in Orthostatic Albuminuria.

GRAM (*Ugeskrift for Læger*, December 22nd, 1921) has for years used Strauss's water test for the functional capacity of the kidneys, and has come to the conclusion that it is both simple and useful. The patient is given a litre of water between 6.30 and 7 a.m., and for the rest of the day he is kept on a dry diet, including bread, butter, eggs, salt, and one apple. The urine passed at 6.30, 7, 8, 9, 10, and 11 a.m., at 2, 5, and 8 p.m., as well as at 5 a.m. next day, is measured. In health most of the litre of water is excreted in the period 7 to 11 a.m. Applying this test to six cases of orthostatic albuminuria the author found that the amount of water excreted in the period 7 to 11 depended largely on whether the patient was up or in bed. In the 7 to 11 o'clock period, when in health, about 1 litre is excreted; he found that if the subjects of orthostatic albuminuria were kept in bed the amount of urine passed varied from 908 c.cm. to 1,578 c.cm., with a mean of 1,173 c.cm. Thus the rate of excretion of water was about the normal. But when these patients were up and about on the day of the test the rate of excretion of water was reduced by more than half in the period 7 to 11 o'clock. The minimum passed in this period was 208 c.cm., the maximum 842 c.cm. In two cases the maximum dilution of the urine was reached an hour later when the patient was up than when he was kept in bed. In two cases of nephritis with albuminuria it was found that confinement to bed during the day of the test diminished the output of water in the 7 to 11 o'clock period, the output being increased when the patients were up and about. The author concludes that this water test is valuable by itself, and when its effects on patients in the recumbent and upright positions are compared a useful clue is obtained in distinguishing between nephritic and orthostatic albuminuria. In contradistinction to most other functional tests this is one which every doctor can carry out in the patient's home.

155. Asthma Due to Constipation.

KRAMER-PETERSEN (*Ugeskrift for Læger*, December 22nd, 1921) considers that the relation of bronchial asthma to chronic constipation is not adequately appreciated, and to show how intimately the one condition may be associated with the other he records in detail two cases, the second of which is particularly instructive. The patient was a woman of 35, who had been subject to asthma for years, and whose symptoms had of late become worse. When she was about to defecate, she experienced a "tightening" of the throat, and on the completion of defaecation an attack of asthma would ensue, lasting about a quarter of an hour. The consti-

pation, from which she had suffered for years, had of late become so severe that there was no evacuation without an enema. She restricted defaecation to every fifth or sixth day, in order to avoid an attack of asthma. She also suffered from pain after food and meteorism, and there were signs of subacid gastritis. Under treatment in hospital with dieting and olive oil enemata at night, she regained the normal action of her bowels and became perfectly free from attacks of asthma. Two years later she reported that the asthma had not recurred and that the action of the bowels was normal. The author quotes Ebstein and Pinz in support of his view that bronchial asthma may be the result of autotoxaemia provoked by disordered functions of the bowels, and he suggests that psychic as well as sensory motor and secretory nervous processes are at work in the chain of events which connects chronic constipation with bronchial asthma.

156. The Diagnosis of Angina Pectoris.

DANZIN (*Arch. Méd. Belg.*, September, 1921) remarks that when a patient appears before an expert complaining of angina pectoris, or of symptoms suggestive of this condition, the following three questions must be answered: (1) Is angina pectoris really present? (2) To what is it due? (3) What is the degree of disability resulting? As regards the first question, voluntary simulation of angina pectoris is not so likely as the fact that the diagnosis of this condition may be wrongly made, as, for example, when there is nothing more than an attack of extra-systole of reflex origin. To determine whether angina pectoris is really present it is not sufficient to auscultate the chest and feel the pulse, but a careful inquiry into the patient's history, and an elaborate clinical examination should be made, including radiocopy, estimation of the blood pressure, and the Wassermann reaction. The symptoms of angina may be due to aortitis when they are brought on by an effort, or to insufficiency of the left ventricle, in which case they usually occur for the first time when the patient is at rest in bed, the attack often being preceded by a period in which the heart has been overworked. In inquiry into the patient's history, special attention should be paid to the possibility of syphilis, chronic nephritis, acute articular rheumatism, or infectious diseases, as these factors may give rise to complicated cardiac lesions. The degree of disability does not depend upon the number, intensity and character of the attacks, but upon the causal lesion. If the condition is due to syphilitic aortitis a pension may be granted if the absence of treatment has been caused by war conditions, especially imprisonment, but not if it has been the result of negligence. When the angina is the result of insufficiency of the left ventricle, the cause and aggravating factors of this condition must be investigated and an award made accordingly. In cases in which no cardiovascular lesion is present no pension should be awarded.

157. Infantile Paralysis.

BORDIER (*Arch. Radiol. and Electrotherapy*, December, 1920) urges the treatment of infantile paralysis (1) by medullary radiotherapy to aid in the restoration of the motor cells of the anterior horns, and (2) by diathermy to raise the chilled limb to normal temperature prior to commencing electrical treatment. For the medullary radiotherapy he employs a series of three consecutive irradiations at the rate of a series per month, with filtration of the x rays by 5 mm. of aluminium. For the diathermy treatment a thin sheet of lead is moulded to the sole of the foot, and another electrode is applied under the buttock. The current is gradually increased in intensity up to 500 or 1,000 milliamperes, the rise in temperature of the limb a little above the ankle being carefully watched, and the current stopped after eight or ten minutes, the limb then being much warmer than its fellow. The treatment is repeated every day for four or five days when the limb temperature will be maintained at normal, and electrical treatment can then be commenced and continued, unless the limb shows signs of returning to a sub-normal temperature when diathermy must be renewed.

158. Epidemic Hiccough.

LANDI (*R. Morgagni*, October 5th, 1921, and *Giorn. di Med. Pratica*, May, 1921) accepts the prevalent view that epidemic hiccough is a variety of encephalitis lethargica. Some cases after a time develop other symptoms of encephalitis. As a rule the symptoms do not last more than two or three days, and are frequently accompanied by some general malaise, headache, shivering, slight fever, and mental irritation. The hiccough may be unilateral—that is, one side of the diaphragm alone may be affected. In epidemic hiccough, as compared with common hiccough, the abdominal muscles share actively in the spasm, and not merely passively. If the hiccough is very frequent, deglutition and sleep may be interfered with. Respiration is not usually affected, the blood pressure is lowered, and there may be a slight excess of sugar in the cerebro-spinal fluid.

SURGERY.

159. The Etiology and Treatment of Ischio-rectal Abscess.

DUDLEY (*Amer. Journ. of Surg.*, December, 1921) finds that only 25 per cent. of cases treated for this condition show complete cure with no sinus remaining. The common sequence of events is as follows: Occurrence of an acute abscess; operative incision; then a persistent sinus complicated often by recurrent abscess formation. True ischio-rectal abscess is practically always secondary to a break in continuity of the anal mucous membrane due to trauma. The condition may be considered potentially as a blind internal fistula in ano with abscess formation. The anal canal is surrounded by two powerful muscles, and it is here that the most solid and traumatizing contents of the bowel pass. Hard scybalous faecal masses may cause a rupture of the mucosa, and infecting organisms have a short path to travel to reach the ischio-rectal fat. This, like all fatty tissue, has a low resistance to bacteria. As suppuration proceeds the fossa soon becomes distended with pus, which early makes its way to the surface. Two main objectives should be aimed at in treatment: first, to evacuate the pus and provide free drainage; secondly, to determine the point of entrance of infection. The usual treatment pays no attention to the source of infection. Thorough dilatation of the sphincter is essential, and the anal mucosa is then inspected and palpated to locate the point of infection. This may be a definite defect or an indurated area of the mucosa. The abscess is incised by an ample radial incision through the involved area and external sphincter muscle. This causes temporary loss of bowel control and puts the parts completely at rest, favouring permanent cure. The wound is packed lightly to its depths with gauze, repeated daily until the wound is nearly healed. Daily hot baths are desirable when available. The relation of tuberculosis to ischio-rectal abscess and fistula has long been a debated question. Dudley finds it is the etiological factor in no more than 2 per cent. of cases.

160. Haemostasis in Suprapubic Prostatectomy.

FISCHER (*Annals of Surgery*, December, 1921) points out that the complications most frequently met with after suprapubic prostatectomy are haemorrhage, shock, uraemia, and sepsis. The three latter conditions can largely be avoided by the two-stage operation and local anaesthesia. Haemostasis is still, however, a source of anxiety to the surgeon. After enucleation a large bleeding cavity is left which freely communicates with the bladder, more or less filled with urine. It is the inability of the surgeon to keep this cavity dry which is responsible for the severe post-operative haemorrhage. Ordinarily the bleeding comes from the vessels in the torn mucous membrane of the bladder and urethra, and is not excessive. The dangerous haemorrhage arises from the bed of the prostate itself, and injuries of the vesical venous plexus are liable to arise in difficult enucleations. Three procedures have been recommended for the control of haemorrhage: Packing with gauze, irrigation with hot saline, and mechanical contrivances such as distended rubber bags. The best means appears to be packing with gauze, and to overcome the soaking loose of the gauze he advises the following method: After removal of the prostate a strip of iodoform gauze is packed tightly into the cavity; this is used as a pattern for the final tampon which is secured by a ligature round its middle and introduced into the cavity. After its introduction the wound edges are tightly sutured with catgut over the tampon. The prostatic cavity is thus completely shut off from the bladder. A tube is placed in the bladder and the ligature lies alongside it. The sutures loosen in a few days and the tampon is withdrawn by pulling on the silk ligature. By using the "lost tampon" method he has had no cases of post-operative haemorrhage.

161. Treatment of Sciatica.

HÖGLER (*Wien. klin. Woch.*, December 22nd, 1921) has treated 21 cases of sciatica by perineural injection of antipyrin, as recommended originally by Heidenhain. Only those cases were selected which had proved refractory to the ordinary treatment, including hypertonic and hypotonic injections of saline solutions and radium therapy. The technique was as follows: 4 to 5 grams of antipyrin, dissolved in 10 c.cm. of distilled water, to which 0.5 to 1 c.cm. of a 0.5 to 1.0 per 1,000 solution of novocain had been added, was employed. The tenderest sciatic point on the buttock was chosen as the site of injection. When the nerve was reached, as was shown by a sharp pain radiating to the toes, the whole solution was injected into the nerve. The great majority of the cases were cured in one to two days. As a rule spontaneous pain and Lasègue's sign completely disappeared in three or four hours after the injection. In 3 cases in which only 2 to 3 grams of antipyrin in 10 c.cm. of distilled water was used, as recom-

mended by Heidenhain, several injections were necessary. The superiority of injections of antipyrin over injections of milk, hypertonic and hypotonic saline solution, and alcohol is that antipyrin acts much quicker and with greater certainty. If a single injection is not sufficient, a second, third, or fourth should be given at intervals of two days. Injections of antipyrin, if aseptic methods are used, are quite free from danger, in contrast with injections of alcohol, in which severe damage to the nerves and permanent paralysis may occur. The only complication observed was an antipyrin rash which lasted two or three days.

162. The Importance of Otitis Media in Infancy.

RENAUD (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, October 20th and 27th, 1921) is convinced that otitis media and suppuration in the petrous portion of the temporal bone play an important part in the pathology of the infant. In seventy autopsies on infants who were supposed to have died of infantile diarrhoea he invariably found extensive suppuration in the aural cavities or in the petrous portion of the temporal bone. Renaud comes to the conclusion that suppurative otitis and suppurative osteomyelitis of the petrous portion of the temporal bone are the essential, if not exclusive, cause of death in infants, and that the presence of this condition renders all spontaneous cure impossible. The practitioner, therefore, should not be misled by gastro-intestinal symptoms in infants. The cachexia is in most cases due to infection and not to hereditary taint or dyspepsia. A systematic examination of the ears should be made in the case of every sick infant. It is decidedly more important than auscultation of the chest, and perhaps even examination of the throat, since the latter if infected can drain itself, whereas an infected ear requires an operation to drain it. Renaud's practice, therefore, if a child does not improve in a few days, is to make an examination for otitis, and if it is absent the prognosis is favourable, while if it is present the prognosis should be very guarded.

163. Post-Pneumonic Gangrene.

WISE and MAYER (*Annals of Surgery*, November, 1921) describe a case of gangrene of the leg arising as a complication of pneumonia from thrombosis high in the femoral artery. A girl, aged 7, developed a typical left lower lobe pneumonia resolving by crisis on the sixth day, but four days later, while apparently in normal convalescence, she developed sudden severe pain in the left thigh just above the knee. A typical dry gangrene developed with a line of demarcation just below the knee, and an isolated area of gangrene over the patella. The thigh was swollen and tender, and pulsation in the femoral artery was absent. Amputation just below the middle of the thigh resulted in an uneventful recovery, but no thrombi were found in the vessels of the amputated limb, the blocking being apparently higher in the femoral artery. There was never any indication of endocarditis, or disease of any blood vessels. The condition of arterial thrombosis or embolism following pneumonia is very rare, embolism of the arteries of the extremities from any cause other than endocarditis being most unusual, and only a very few similar cases have been reported. With a normal heart and clear previous history the pneumonia followed by arterial embolism or thrombosis seems to be cause and effect, and it is easy to understand an embolism from the lungs reaching the systemic circulation.

164. Echinococcosis and Actinomycosis of the Spine.

GULEKE (*Deut. Zeit. f. Chir.*, 1921, cxvii) records a case of echinococcosis and one of actinomycosis of the spine. In the first patient, a male aged 46, a hard tumour at the level of the second and third dorsal vertebrae, extending outwards in the left supraclavicular region, caused well-marked signs of compression of the cord and was regarded as an osteosarcoma; aminectomy being performed, it was found that numerous echinococcus cysts had destroyed almost the whole of the first rib on one side and had invaded the vertebrae and spinal canal. Hydatids were found in the posterior mediastinum also, and death resulted from bronchopneumonia. In the second patient, a man aged 53, a mass of actinomycotic tissue with characteristic sulphur-like granules occupied the space between one scapula and the chest wall; in spite of five operations it was not found possible in five years to eradicate the infection, which had spread to the posterior mediastinum and caused a superficial caries of the dorsal vertebrae. Symptoms of pressure on the cord were relieved by several removals of neural arches and the corresponding transverse processes; actual paralysis was not produced. In this case the primary focus appeared to have been situated in the upper lobe of the right lung; the infection extended backwards into the mediastinum, but the pulmonary lesion had become completely arrested.

OBSTETRICS AND GYNAECOLOGY.

165.

Treatment of Eclampsia.

ACCORDING to HOFBAUER (*Zentralbl. f. Gynäk.*, December 17th, 1921) the eclamptic convulsion marks the culminating point of a pathologically increased action of the internal secretion of the pituitary gland on the blood vessels of certain tissues, notably the brain, liver, kidneys, and skin. The treatment of eclampsia should, therefore, be based on the principle of preventing or abolishing morbid increases of pituitary function. It is of great importance to reduce the blood pressure, and it is by this rather than by a detoxicating action that venesection is beneficial. Chloral hydrate and the allied hypnotics, on account of their depressing action on the respiratory centre and the consequent danger of oedema of the lung, must be used cautiously, and only in the early stages of treatment. The value of the nitrites is diminished by the fact that they cannot be administered except by the mouth. The author regards the exhibition of ovarian extract or of corpus luteum extract, or of both, as a most important therapeutic measure in the treatment of eclampsia; these extracts have the property of diminishing the blood pressure, of antagonizing the secretions of the hypophysis and suprarenal gland; they also have an elective action on the cerebral blood vessels, and finally, given intravenously, they have the property of diminishing the coagulability of the blood. An auxiliary means of treatment is the administration of citrates.

166. LICHTENSTEIN (*Zentralbl. f. Gynäk.*, January 7th, 1922) records 316 cases of eclampsia treated during the last ten years, with a maternal mortality of 8.5 per cent. and a foetal mortality of 18.8 per cent. among the viable. The treatment adopted consisted in venesection, the exhibition of narcotics, saline infusions in certain cases, and abstention from inducing or accelerating labour except in cases in which the os was fully dilated.

Toxic substances
a fall of blood pressure, or diminishing capillary stasis and accelerating circulation in the arterioles and capillaries, and lastly, of facilitating tissue respiration. The first bleeding is of 500 to 600 c.c. when delivery is not immediately expected, and of 250 to 300 c.c. when delivery is shortly impending. If the os is fully dilated so that delivery may be expected at once the first venesection is deferred, and when given after delivery is regulated according to the amount of blood lost at labour. Subsequent venesections of 500 to 600 c.c. are made and repeated if necessary. The narcotics given consist of morphine or combinations of opium derivatives together with chloral hydrate. The advantages claimed for abstention from rapid induction of labour are that: (1) Many cases of eclampsia as a result of this expectant treatment become cured without the pregnancy being terminated; in the author's series this took place in 97 per cent. of the *ante-partum* and 16 per cent. of the *intra-partum* cases, sometimes with the issue of a living child. (2) There is diminished risk of severe bleeding and of infection, both of which constitute real dangers associated with achievement of force. (3) There is no post-operative risk of formation of fistulae or of cervical or corporeal scars. (4) Both maternal and foetal mortality are reduced to one-half. (5) The treatment is well adapted to non-institutional practice.

167. Differential Diagnosis of Glycosuria and Diabetes in Pregnancy.

ACCORDING to SALOMON (*Munch. med. Woch.*, 1921, lxxviii), cases of glycosuria in association with pregnancy may be divided into three groups. The cases of the first group are characterized clinically by the constant presence of a uniformly low percentage of sugar in the urine. Estimation of the blood sugar shows that during starvation it amounts to 0.1 per cent. or less, and one hour after administration of 50 grams of sugar the value is unaltered or slightly increased, remaining, however, below 15 per cent. If a repetition of this test gives a similar result the case may be definitely classified as one of glycosuria of pregnancy. The second, or intermediate, group of cases is one in which tolerance for carbohydrates is retained to a certain degree, and the starvation blood sugar is as low as in the first group, but hyperglycaemia (that is, presence of more than 0.15 per cent.) ensues when a carbohydrate diet is given. A case can only be assigned to this class after careful consideration of the clinical findings in combination with laboratory tests. In the third group of cases the amount of sugar in the urine is considerable, the blood sugar value even on a starvation diet is greater than 0.15 per cent., and is still more increased by the administration of carbohydrates; this must be regarded as a condition of true diabetes. The great majority of cases investigated are found to come within the first group.

168. Veronal in the Vomiting of Pregnancy.

JACOBÆUS (*Ugeskrift for Læger*, December 29th, 1921) notes as curious that since veronal was introduced in 1903 only two papers have appeared on its action in the vomiting of pregnancy. One of these papers was by Rowland, who reported a case in which a veronal enema proved remarkably effective (*BRITISH MEDICAL JOURNAL*, 1906, ii, p. 1490). The author has found it act most promptly in both his private and hospital practice, and he records in detail two hospital cases which were characterized by the severity of the vomiting. His dosage varied from 40 to 60 cg., given in the evening, and he believes that suggestion can be put out of court as the cause of the success achieved, for the exhibition of other drugs, such as adalin, failed to give relief. In both cases the vomiting ceased soon after veronal was given, and with the return of the vomiting after a shorter or longer interval, the renewed prescription of veronal was again successful. It was observed that some time elapsed between the withdrawal of the drug and the return of the vomiting, which at first was slight, and which gradually increased in severity. The author correlates this observation with the fact that the excretion of veronal is slow. He discusses the underlying causes of the vomiting of pregnancy and notes its similarity to sea-sickness, which he has also found to react promptly to veronal.

169. Treatment of Puerperal Infection by Douches of Dakin's Fluid.

ANDERODIAS (*Gynéc. et Obstét.*, 1921, iv, 5) after a three years' trial writes favourably of the effect of douching with Dakin's fluid in the treatment of puerperal infection. Carrel's tubes were found to be ill adapted for vaginal or uterine use, and the writer employed a cylindrical hollow gum-elastic sound with a single termino-lateral perforation; this was introduced, after careful cleansing of the vagina and cervix, into the uterus, the other extremity being fixed to the thigh by a bandage or plaster. Dakin's fluid to the amount of 40 to 50 c.cm. was injected every two hours during the day and every three hours during the night from a reservoir placed at a height of 75 to 100 cm. Of 152 patients treated by this method 133 were cured within two to eight days; if well-marked amelioration of local and general conditions has not been obtained in this time, the use of the solution should be abandoned and other steps taken. It is admitted (1) that the treatment was most strikingly successful in cases characterized by infected vaginal, cervical, or vulvo-vaginal wounds, the sound being placed in the vagina and not the uterus; (2) that other therapeutic measures were employed contemporaneously; (3) that the records lack information furnished by bacteriological examinations. Nevertheless, the impression was formed that great benefit followed in the majority of cases. Of the 15 unsuccessful cases the mortality is not stated; three were associated with extra-genital foci of infection—bronchopneumonia, pleurisy, and pyelonephritis respectively. It may be suggested that part of the efficacy of the treatment was due to the continuous uterine drainage.

PATHOLOGY.

170. Relationship of *Treponema pallidum* to Lymphoid Tissues in Experimental Syphilis.

THE experimental study of syphilis in the rabbit has been carried on for some years with striking results by BROWN and PEARCE. They now (*Journ. Exp. Med.*, January, 1922) report a very interesting piece of work on the dissemination of the virus by means of the lymphatic channels. If a rabbit be infected by scrotal inoculation and one of the inguinal nodes be removed two days later and injected into the testicle of a normal rabbit, the latter develops an orchitis about thirty days later. This shows that the spirochaetes must be present in the regional lymphatic glands at a very early period after infection—before, in fact, any local change has appeared in the scrotum. Further, if the scrotum be removed two days after infection, the animal still develops generalized syphilis, just as it would have done had the local focus been left intact. During the progress of the disease in rabbits it is usual for the popliteal glands to become enlarged. It was found that the injection of such a gland into a healthy animal, even when no infected area was drained by the gland, resulted in the development of syphilis. It would appear, then, as if the lymphatic glands served as a refuge place for the spirochaetes. To test the length of time that this effect might last, a series of rabbits which had been infected several months previously and which had passed into a latent stage were taken, their popliteal glands removed, emulsified in saline, and injected

into fresh rabbits. In every case syphilis developed, showing the constant presence of the *Treponema pallidum* in these glands during the latent stage of infection. Similar results were obtained in the case of rabbits which had been treated with arsphenamin, which caused the disappearance of clinical symptoms without, however, destroying the organisms in the glands. These experiments demonstrate that the disease is not confined to the site of local inoculation, but that lymphogenous dissemination regularly takes place, and that during the course of this process organisms become localized in the lymph nodes and exist there indefinitely, irrespective of the occurrence of manifestations of the disease.

171. The Blood in Tetrachlorethane Poisoning.

MINOT and SMITH (*Arch. Int. Med.*, December, 1921) report investigations carried out in tetrachlorethane poisoning to ascertain whether any abnormality occurs in the blood, and whether mild poisoning can be anticipated by blood examination, sixty-eight employees in an artificial silk plant being observed for a period of five months. The onset of poisoning is marked by fatigue, free perspirations, drowsiness, anorexia, nausea and vomiting, constipation and headache, with later jaundice, hepatic tenderness, pallor, and an increase in the gastric and nervous symptoms. The blood of twenty-five employees showed distinct abnormalities, especially an increase of the large mononuclear cells, sometimes amounting to 40 per cent. In addition to this progressive increase in the large mononuclears, there was a progressive increase in the young large mononuclears, some formed and some broken; a somewhat elevated white count; slight but progressive anaemia, and a slight increase of platelets. The blood changes can usually be detected before any clinical symptoms develop, thus proving the value of blood examination in the prevention, and in the diagnosis and prognosis, of poisoning by tetrachlorethane. A percentage of large mononuclear white cells above twelve is the first sign, and an indication for close observation, though such a percentage is not necessarily followed by clinical developments. The presence of a considerable number of young large mononuclears, some formed and many broken, is indicative of a severer condition than when the same number of more mature, large mononuclears are present. The value of such examinations in the regulation of the employment of exposed persons is obvious.

172. Blood Culture in the Diagnosis of Typhoid Fever.

SVARTZ (*Hygiea*, December 31st, 1921) draws attention to the differences of opinion still existing as to the diagnostic value of blood cultures in typhoid fever, and she notes that the proportion of positive results depends largely on the blood being examined at once and the test being repeated when the first examination is negative. The value of the test is appreciably reduced when the blood has to travel a considerable distance after being drawn. At the Serafimer-lasaret the author has examined the blood in 40 cases of typhoid, and in all the 12 cases examined in the first week of the disease she obtained typhoid bacilli on culture. Positive results were obtained in 16 of the 22 cases examined in the second week, in 4 of the 5 examined in the third week, and in 1 of the 2 examined in the fourth week. Thus she found typhoid bacilli in the blood of 33—that is, in 83 per cent. This proportion would have been still higher had all the negative tests been repeated. Two of her cases were particularly instructive. One was that of a patient whose temperature in the eighth week of the disease was 37.5° to 38.3°C. Typhoid bacilli were obtained from the blood at this stage. Five days later, and after the patient had been afebrile for four days, the blood was again examined but no typhoid bacilli could be found. The other case was that of a patient who had been afebrile for eighteen days, had been up and felt perfectly well when in the ninth week the temperature again suddenly rose. Culture of the blood on the second day of the fever proved negative; but two days later a new culture yielded numerous typhoid bacilli.

173. Diagnosis of Tuberculosis by the Reaction of Fixation.

ICHOK (*Arch. Méd. Belges*, October, 1921), as the result of the examination of the reaction of fixation in 115 tuberculous cases and 38 non-tuberculous subjects, came to the conclusion that the reaction of fixation with Besredka's antigen is specific, though a positive result is occasionally found in syphilitic patients who are not tuberculous. In dormant tuberculosis the reaction was positive in 53 out of 56 cases, or in 94.3 per cent.; in active forms of the disease, without marked signs of intoxication, the reaction was positive in 47 out of 50 cases, or in 94 per cent., and in rapidly destructive forms and forms accompanied by signs of severe intoxication the reaction was positive in 3 out of 9 cases, or in 33.3 per cent.

Direct clinical evidence to the value of 'Iodolysin'

A soluble compound of 'Thiosinamin' containing 4.7 per cent. of Iodine, which has given strikingly successful results in the treatment of Rheumatism, Rheumatoid Arthritis and Arthritis Deformans

"NO AGENT SO EFFECTIVE"

"A lady was sent to me several months ago suffering from advanced Rheumatoid Arthritis. Knee, wrist and ankle joints were all affected. In a word she was a complete cripple. After six weeks treatment she was able to walk well and movement was possible in all joints which formerly were in a state of ankylosis. In my own opinion there is no medicinal agent so effective in the treatment of Rheumatoid Arthritis as 'Iodolysin'." M.B.

"UNIFORMLY SUCCESSFUL."

"I have used 'Iodolysin' in a very large number of cases with uniformly successful results. Typical is that of a lady age 48 of obese habit. She was so affected as to be scarcely able to move. 'Iodolysin' in 20 minim doses was prescribed together with 'Iodolysin' Ointment for local application to the joints. She was completely relieved for the time and keeps well and free from pain when treatment is instituted for short periods every 18 months." M.D.

ENFORCED UNEMPLOYMENT REMEDIED.

"I am pleased to be able to testify to the very excellent results which I have obtained from a fairly extensive use of 'Iodolysin' particularly in cases of Rheumatoid Arthritis. Cases of long standing disability and enforced unemployment through stiff and crippled joints have been so much alleviated that they have been able once more to earn their own livelihood. The patients tolerate the drug perfectly well, and I have had no trouble with nausea or any unpleasant effects." M.D.

The Original and Standard Emulsion of Petroleum

ANGIER'S EMULSION

Angier's Emulsion is made with Petroleum specially purified for internal use. It is the original petroleum emulsion—the result of many years of careful research and experiment.

Influenza and Sequelæ.

The unique soothing properties of Angier's Emulsion and its favourable influence upon assimilation and nutrition, make it eminently useful both during and after Influenza. It has proved most efficacious in relieving the catarrhal symptoms, whether tonsillar, bronchial, or intestinal; also, in combating the nervous depression and debility. After the attack, or when the patient's nutrition and vitality are at the lowest ebb, try the continued use of Angier's Emulsion for convincing proof of its effects as a tonic and restorative.

Bronchitis, Sub-Acute and Chronic.

There is a vast amount of evidence of the most positive character proving the efficacy of Angier's Emulsion in sub-acute and chronic bronchitis. It not only relieves the cough, facilitates expectoration, and allays inflammation, but it likewise improves nutrition and effectually overcomes the constitutional debility so frequently associated with these cases. Bronchial patients are nearly always pleased with Angier's Emulsion, and often comment upon its soothing, "comforting" effects.

In Gastro-Intestinal Disorders.

of a catarrhal, fermentative, ulcerative, or tubercular nature, Angier's Emulsion is particularly useful. It exercises sedative, demulcent, lubricant effects throughout the entire intestinal canal, and it restores tone to all the digestive functions. Moreover, it offers the very best vehicle for the administration of astringents and antiseptics (bismuth, salol, &c.). The Emulsion may be administered undiluted, or in any desired vehicle.

Hunterian Lecture

ON THE

NATURE AND CAUSE OF OLD-AGE ENLARGEMENT OF THE PROSTATE.

BY

PROFESSOR KENNETH M. WALKER, M.A., M.B., F.R.C.S.,

LECTURER IN VENEREAL DISEASES, ST. BARTHOLOMEW'S HOSPITAL;
SURGEON TO OUT-PATIENTS, ROYAL NORTHERN HOSPITAL.

THERE are few problems in medicine that have attracted more attention or given rise to a greater diversity of opinion than the problem of the nature and cause of enlargement of the prostate. One has only to glance through medical literature since the first reference to the subject by Nicola Massa, a Venetian physician of the sixteenth century, to realize how much research has already been expended on this subject and how little we really know concerning the genesis and pathology of the condition. In venturing, therefore, to make it the subject of my lecture on this, the second occasion that you have done me the honour of inviting me to address you, I would claim your special indulgence. Far abler investigators than myself have failed to throw any fresh light on this subject. In my humble opinion their failure has not infrequently been due to the fact that they have viewed the problem from too narrow an angle—as a surgeon, as a pathologist, or as an anatomist, as the case might be. For this reason I have tried to stand further back from my subject and to take as wide a view of it as possible, in the hope that where my investigation might fail in depth of vision it would gain in breadth. I have even included in its scope a consideration of enlargement of the prostate occurring in animals other than man, and an investigation of its incidence amongst the various races of the world. I have done this not only because I believed it to be the best method of tackling the subject of prostatic enlargement, but also because I am convinced that it is in the manner in which all research should be pursued. The days of working in watertight compartments are over, and if in the future we are to continue making progress there must be a closer liaison not only between medicine, surgery, and pathology, but also between these and the kindred sciences of comparative anatomy, anthropology, and veterinary surgery.

The Frequency of Prostatic Enlargement.

Before going further into the subject it is advisable to lay down clearly that I propose to limit my inquiries to the investigation of only one type of enlargement of the prostate—the glandular, or what is commonly known as the adenomatous prostate. Of inflammatory enlargements of the fibrous type, and of carcinoma, I shall say little or nothing.

The first point to strike anyone who conscientiously examines prostates, whether his examination be made in the post-mortem room or in the out-patients' department, is the frequency with which some degree of enlargement occurs after the age of 50 has been reached. This, of course, is more obvious in the post-mortem room than in the out-patients' department, for it is only by means of such special examinations as cystoscopy and posterior urethroscopy that many of the lesser degrees of enlargement can be diagnosed during life. As an indication of the commonness with which this increase in the size of the prostate occurs after the age of 50 I have produced a curve which represents the size of the prostate in the various decades of life. (Fig. 1.) This curve has been constructed mainly from data supplied by Lowsley in his extensive work on the size and form of the prostate from birth to old age. It will be seen from the curve that the maximum size is reached somewhere about the age of 60. After this period there is a slow diminution

in size with the advent of senility. It may therefore be accepted that some degree of enlargement after the age of 50 is the rule rather than the exception. This fact has been emphasized by such writers as Sir Astley Cooper, and notably by Sir Benjamin Brodie, who wrote:

"When the hair becomes grey and thin, when atheromatous deposits invade the arterial walls, when there is formed a white zone about the cornea, at the same time ordinarily, I dare say invariably, the prostate increases in volume."

However, although this is so, it must be remembered that only a percentage of those whose prostates show enlargement suffer any disability therefrom. There is no direct relation between the degree of enlargement and the severity of the symptoms. It is indeed by no means rare to find in the post-mortem room a prostate weighing as much as 40 grams, which has not produced any symptoms during life. What is still more interesting is the fact that enlargement of the prostate during the latter part of life is by no means a prerogative of the human race. Of its incidence amongst domestic animals I cannot yet speak with any degree of certainty, owing to the difficulty I have encountered in obtaining specimens of uncastrated animals dying of old age. Amongst dogs, at any rate, it is extremely common, and, as old dogs are easily obtained, much of my work has been done on that animal. However, from the material which has been put at my disposal by the courtesy of the Veterinary College and the Zoological Society, I believe there to be a general tendency throughout the whole animal world towards enlargements of the secondary sexual glands in old age.

The Nature of the Enlargement.

Not only are we in complete ignorance as to the causes underlying enlargement of the prostate, but we are in doubt as to the nature of the enlargement itself. Is it a hyperplasia following previous inflammation, or is it in the nature of a neoplasm? The most convenient method of dealing with the subject will be to pass under review the theories of enlargement which have at various times been put forward, and to see whether they fit in with ascertained facts.

These theories may be considered under three headings:

1. The inflammatory theory.
2. Neoplasms.
3. Degeneration theories.

The Inflammatory Theory.

The possibility of prostatic enlargement being due to an inflammatory process was suggested by De Saull as long ago as 1813. Since then the theory has been upheld by a great number of authorities, and especially by Rotschild and Ciechanowsky.

This latter observer maintained that no true increase of gland tissue occurred with enlargement of the prostate. The increase he regarded as only apparent, and due to dilatation of the glands. According to Ciechanowsky, the dilatation was the result of blockage of the prostatic ducts following inflammation in the surrounding struma. The obstruction of the ducts resulted in the accumulation of secretion in the acini and their gradual dilatation. The chief cause of enlargement of the prostate would (according to this theory) be previous attacks of inflammation, and particularly of inflammation in the struma surrounding the prostatic ducts.

This inflammatory theory has received so much support that no apologies need be offered for dealing with it at some length. Infection is one of the commonest causes of cell proliferation that we know, and the urethra and the prostate are particularly exposed to infective processes. As an illustration of the seductive nature of the theory, claiming as it does a simple and easily acceptable explanation of enlargement, I am convinced that it is insufficient to explain the type of prostate under present consideration. My reasons for refusing to accept the inflammatory theory, as put forward by Ciechanowsky, are as follows:

1. That as a rule signs of inflammatory reaction are absent in sections of enlarged prostate. It is true that occasionally a round cell infiltration is to be found, but I believe this to be a secondary

FIG. 1.—Curve showing average size of prostate at various ages (thick continuous line), and prominence of Leydig's interstitial cells (interrupted line).

condition and one that is dependent on a superimposed sepsis of the urinary tract. When the frequency with which sepsis follows prostatic enlargement is remembered the occasional appearance of a round-cell infiltration in such sections is not surprising.

2. That I have never succeeded in demonstrating organisms in microscopic sections of enlarged prostate. These negative results are in conformity with those obtained by Dudgeon and Cuthbert Wallace. It is true that these observers by means of cultural methods succeeded in obtaining evidence of organisms in enlarged prostates, but the low grade pathogenicity of the organisms obtained was strongly against their being responsible for the condition of enlargement.

3. If enlargement is due to dilatation of existing glands rather than to proliferation, a direct relationship should exist between the size of the prostate and the degree of glandular dilatation that has taken place. "Ex pede Herculem." No such relation exists. In other words, it is impossible for a person who examines a microscopic section to state whether it comes from a very large or only a moderate-sized prostate. Dilatation, moreover, of glands is not infrequently found in old prostates showing no enlargement whatever.

4. No clinical relationship can be established between enlargement of the prostate and previous urinary infections, whether gonococcal or otherwise. As will be subsequently shown, enlargement is particularly rare in the very races that suffer most from venereal disease.

The Adenoma Theory.

The adenoma theory has been supported by Socin, Cohnheim, Rindfleisch, Cuthbert Wallace, Velpeau and the French school of Pathology. It is probably the view that is most commonly held at the present time, but the arguments against it are very strong. While I agree that the type of enlargement we are considering may supply conditions favourable to the formation of definite neoplasms, I am convinced that the enlargement itself is not neoplastic in origin. The arguments against the neoplastic theory are as follows:

1. In order to explain the condition found in enlargement of the prostate we should have to postulate the appearance of multiple adenomata not only in the prostate itself but in the peri-urethral, subcervical, and in certain cases the subtrigonal glands, for, as we shall subsequently see, enlargement of the prostate is not an isolated phenomenon, but is associated with widespread changes in the genital tract.

2. Adenomata are not common at the age at which prostatic enlargement occurs.

3. If we examine a microscopic section we find that the newly formed glandular tissue reproduces the original prostatic tubules with extreme fidelity. They are often indistinguishable from normal prostatic glands, and, as has been shown by Herring, they are provided with well formed ducts. They also secrete a fluid similar to prostatic fluid, but containing more fat. The tissue of a tumour, on the other hand, is almost invariably atypical, and with rare exceptions it does not develop the physiological properties of the organ in which it develops.

Theories of Degeneration.

On *a priori* grounds there is much to be said in favour of a theory that regards enlargement of the prostate as a degenerative process overtaking an organ that has passed its period of full functional activity. Although a man of 55 may be regarded as comparatively young, yet from the point of view of his reproductive system he is old. It is true that active spermatogenesis may be seen in the seminiferous tubules of a nonagenarian and that the sexual life of the male has no abrupt termination. The menopause in his case is so gradual in its onset as to be almost imperceptible. Nevertheless a decline in sexual activity occurs, and the genital tract of a man of 55 bears unmistakable signs of involution. Launois was one of the first to suggest that enlargement of the prostate is but a part of a degenerative fibrosis taking place throughout the whole urinary apparatus, kidney, bladder, etc. The cause underlying this degeneration he considered to be arterio-sclerosis. This view was supported by Gnyon and many others. However, although Launois was undoubtedly right in drawing attention to the fact that prostatic enlargement is a part of a general change, it cannot be said that subsequent observations, including my own, have shown that this change is necessarily associated with arterio-sclerosis. Ciechanowsky, Casper, and Motz have all failed to find evidence that arterio-sclerosis is the cause underlying prostatic enlargement, and in my own series of cases not more than 10 per cent. showed arterial thickening. When the age of these cases is taken into consideration the occasional existence of arterio-sclerosis is not surprising.

Other observers have suggested that the prostatic condition is secondary to changes in the testes rather than to the presence of an arterial lesion. The relation between the testes and the prostate is a very close one, especially during the first half of life, and the theory is a plausible one. In order to test it I have made a careful examination of the testes associated with enlargement of the prostate, both as regards their relative weights and their histological appearance. I have entirely failed to establish any relation between the weight and naked-eye appearance of the testes and the size of the prostate. Microscopic examination of testes shows, however, the existence of changes that are undoubtedly degenerative in nature. The basement membrane of the tubules is thickened and the interstitial cells of Leydig are scanty, and in some cases obviously degenerating. In sections stained with Scharlach R. the cells of the tubules show the presence of numerous coarse granules. That these granules are due to the formation of fat in cells undergoing degeneration can be shown by suitable methods of staining and by the use of crossed prisms. However, although signs of degeneration of the tubules are undoubtedly present, spermatogenesis is by no means arrested.

In eight out of eleven prostatic cases I found active spermatogenesis to be present. Of the three cases in which it was absent two had suffered from malignant prostates, and, as Mott has shown, spermatogenesis is in any case absent in cases of malignant disease. A point of especial interest in connexion with these sections was the fact that the degenerative processes were distinctly patchy in distribution—that is to say, one tubule would show obvious changes and cessation of spermatogenesis, whilst another would appear to be fairly normal.

As a control the testes of men of equal age, but without enlargement of the prostate, were examined. Similar changes to the above were found in these controls.

It must therefore be concluded that the alteration in the testes that are associated with enlargement of the prostate do not differ in kind (although they may be slightly greater in degree) from the changes that normally take place in the testis at the end of active sexual life.

Having reviewed the theories that have been advanced to explain the condition, it will next be advisable to make a brief survey of some of the distinguishing features of prostatic enlargement, including its macroscopic and microscopic appearance. We shall then be in a position to see whether there is any other theory which offers a more satisfactory explanation of the condition.

The Site of the Enlargement.

The first point to be considered is the precise situation in which the increase in size occurs. What part of the prostate is most commonly affected? The fact that so many of our statistics on the subject have been drawn from surgical sources has led to an exaggerated idea of the rôle played by the middle lobe in this matter. Increase in the size of this lobe is, of course, almost invariably productive of symptoms, and it is on this account rather than because the middle lobe has any monopoly in enlargement that such emphasis has been laid on it. By far the commonest form of enlargement (over 70 per cent. of my cases) is one which involves lateral and middle lobes alike. Indeed, there is only one portion of the prostate which does not take part in enlargement, and that is the posterior lobe. So few are the exceptions to this rule that I have been tempted to believe that the prostate (concerning whose functions we know so little) is in reality a composite gland, the posterior lobe of which differs, not only in histological structure but also in its function, from the rest of the gland. At any rate, there is sufficient ground for the belief that the posterior lobe has an individuality of its own, and one of the points of difference between it and its fellows is the fact that although it is not infrequently the starting point of a carcinoma it scarcely ever takes part in a non-malignant enlargement.

Motz and Pearnan have advanced the view that what has been termed enlargement of the prostate is in reality not an enlargement of the prostate proper but rather of the submucous glands. The situation of the glands to which these authors have accorded so important a rôle is best seen in a section through the posterior urethra and bladder neck somewhere about the fifth foetal month. Fig. 2 is from a diagram of Lowsley's, and shows that the glands are arranged in three groups: (1) The urethral (Albarran's glands); (2) the subcervical; and (3) subtrigonal. The names given to the different groups sufficiently describe their situation. There is one point, however, that is worthy of emphasis, and that is

the fact that the subcervical group of glands is separated from the prostate proper by the interposition of the bladder sphincter. The fact that the subcervical glands lie internal to the sphincter gives support to the view that they rather than the prostate play the chief part in obstructions in the neighbourhood of the vesical neck, and in intravesical projections (specimen). However, whilst readily admitting that these glands, rather than the prostate itself, are in many cases the cause of an obstruction, Motz and Percarnan have, in my opinion, gone too far in denying all responsibility to the prostate. The truth, as is so often the case in arguments, scientific or otherwise, would appear to be that both statements are correct. Some cases of enlargement are mainly prostatic, whilst others are mainly submucous. It is difficult, if not impossible, to estimate the percentage of cases in which the obstruction is mainly submucous and that in which it is chiefly prostatic. However, as a rough indication of the frequency with which alterations in the submucous glands are encountered we have Lowsey's statement that in men over 30 Albarran's group of glands are enlarged in 25 per cent. of cases and the subcervical group in 22.8 per cent. Similarly, J. R. Caulk, as the result of the examination of 485 cases of clinical obstruction, found enlargement of Albarran's glands in 97 (20 per cent.).

Prostatic Enlargement a Part of a Condition Affecting the Whole Genital Tract.

Already we have accumulated sufficient evidence to justify the statement that enlargement of the prostate is not an isolated phenomenon, but is associated with changes in other portions of the genital tract. These changes (which, at any rate in the case of testis, are definitely degenerative in nature) are found in the testis, the prostate proper, the peri-urethral, subcervical, and subtrigonal glands. There is also evidence that the vesiculae seminales may be implicated. In a great many cases they are found to be enlarged and thickened. According to Lowsey, this occurs in 32 per cent. of men over the age of 30. In certain instances the dilatation and thickening of the vesicles may be indirectly due to pressure on the ejaculatory ducts, but in others the change is a part of the degenerative process affecting the whole genital tract.

FIG. 2.—Sagittal section through post-urethra and bladder neck; fifth month (after Lowsey), showing developing prostate and submucous glands.

Section of Enlarged Prostate.

The following are the naked eye and microscopical appearances:

Naked Eye Appearance.—A section through an enlarged prostate reveals the presence of a number of small round opaque areas of a colour that varies from white to a pale yellow. These areas are scattered throughout the substance of the gland. By the advocates of the neoplasm theory they have been regarded as adenomata. They are surrounded by a capsule of translucent normal prostatic tissue, from which they can be enucleated with comparative ease. In certain cases these primary areas are subdivided into secondary smaller ones. Similar areas are to be seen in the enlarged prostate of a dog.

Microscopic Appearance.—A microscopic examination shows that the opaque masses or nodules described above are formed of glandular tissue. In a single section may often be seen different phases in their development. This is especially the case if the dog be selected for the purpose of their study.

At an early stage in the formation of one of these masses there is an active proliferation of the endothelial lining of a group of glands. The proliferation is mainly directed to the formation of a large number of intra-acinous growths, which become more and more luxuriant as time goes on. As a result of the enlargement occurring in these central glands the surrounding tissues with their glands become disposed concentrically around the area of proliferation so as to form a capsule. The formation of intra-acinous growths in time becomes so luxuriant that a section through one of these areas of proliferation resembles nothing so much as a section through a papilliferous ovarian cyst. In frozen sections stained with some such dye as Schärlach R. it will be seen that in certain areas these proliferated glands are undergoing marked fatty degeneration. The microscopic appearances in the human prostate are similar to the above, although less striking. There exists the same tendency to the formation of intra-acinous growths, and there are the same patches of fatty degeneration.

Although there might seem to be little in common between the above and the changes that have previously been described as occurring in the testes associated with the enlargement,

the similarity is greater than would at first sight appear. In both testis and prostate we have a degenerative process that picks out certain tubules whilst it leaves others more or less intact. In the gland cells of either organ we note the same structural alterations—namely, an enormous increase in the size and number of granules that take on a red stain with Schärlach R. In both instances this fatty degeneration is patchy in its distribution throughout the organ and is associated with an increase in the interstitial fibrous tissue. The chief difference lies in the fact that whereas the tubules of the prostate have undergone a previous proliferation, those of the testis have not.

The Cause of Enlargement.

An enlarged prostate is, therefore, according to this view, to be regarded as a prostate that has undergone a form of degeneration which, for the sake of convenience, we may term fibro-epithelial. The condition may be considered in the light of an accident that has occurred during the period of involution of the genital tract. If we look for an analogy to this in the case of the female we may find one in the somewhat obscure condition known as a sero-cystic disease of the breast. The breast, like the prostate, is one of the secondary sexual glands. It is in intimate association with the ovary, just as the prostate is with the testis. Finally, the breast shares with the prostate the same tendency to develop lesions during the period of sexual decline. When we examine a microscopic section of a breast that has become enlarged as the result of sero-cystic disease, we find that it presents a very close similarity to that of an enlarged prostate. We find the same formation of intra-acinous

growths as the result of epithelial proliferation. There is the same tendency to dilatation of the acini, and an equal absence of round-celled infiltration, or of other signs of inflammation. Moreover, the changes in the breast show the same patchy distribution that we have seen to be characteristic of the prostatic condition, one group of glands being markedly affected whilst another remains free. The most obvious difference between the prostatic

and the breast lesions is the presence of fatty degeneration in the former case and its absence in the latter.

The difficult question now arises as to what are the causes that determine the onset of fibro-epithelial degeneration. Why should one prostate undergo an enormous enlargement whilst another to all intents and purposes escapes? We have seen that infection alone fails to account for the condition, although it may possibly act as a contributory cause. Is there any reason to suppose that any of the other causes that have been put forward at various times exert any real influence? It has been suggested that congestion may determine the onset of enlargement. We know that chronic engorgement may cause hyperplasia, and there are reasons for believing that the prostate is particularly prone to congestion. The frequency with which a thrombosis of the plexus of Santorini is found in the prostate at necropsy is sufficient evidence of the liability of this organ to venous stasis. But although there exists an antecedent probability that venous congestion may be a contributory cause, it is unlikely that it is of more than secondary importance. Other possible explanations must therefore be examined.

The Relation of the Prostate to the Endocrine System.

The intimate relationship of the prostate to the interstitial cells of Leydig in the testis is well known. Through Leydig cells the prostate becomes linked with the other endocrine glands, and notably with the suprarenals and the pituitary. The relationship between the prostate and the pituitary has indeed been directly demonstrated by Cretsch, who found that, in feeding experiments upon young hypophysectomized rats, anterior lobe stimulated the growth of the prostate whilst posterior did not. But in addition to this well-established connexion between the prostate and the endocrine system, a claim has been advanced by certain observers that the prostate itself is responsible for the elaboration of an internal secretion. The evidence in favour of this, although suggestive, is very far from being conclusive, and is chiefly based on the work of Machi.

Macht fed tadpoles on prostatic fluid and demonstrated that it hastened differentiation and metamorphosis; but to a less extent than did thyroid extract. He also found that injections of the extract provoked contraction of the genito-urinary organs both in the male and female (that is, uterus, bladder, ureters, etc.). Attention has, moreover, frequently been called to the fact that mental symptoms are particularly prone to develop after prostatectomy. Macht, however, as the result of a series of ingenious experiments on prostatectomized rats, showed that in the case of these animals cerebation was unimpaired by prostatectomy. The mental symptoms following prostatectomy should, therefore, in the light of what we have found, be correlated with the degenerative processes that have taken place in the testes, rather than with any removal of prostatic secretion.

My own observations, as far as they go, indicate that injections of extract of prostate in the human being do not produce any response in the way of alteration of blood pressure, pulse, respiration, etc. I have used both an autolysit and a commercial preparation of prostatic extract for this purpose and have never obtained a reaction that could be appreciated clinically. Incidentally I may mention that I have found that prostatic extract, when employed as a therapeutic measure, is occasionally of use during the early phases of enlargement, but of little benefit in the later.

As a final piece of evidence in favour of the prostate furnishing an internal secretion is the case reported by Doré, in which prostatectomy was followed by a marked hypertrophy of the breasts.

Apart from the above considerations the close dependence of the prostate on the ductless glands during its period of development affords sufficient ground for considering carefully the possibility that enlargement may be associated with some change in the endocrine system. The menopause in the female is generally accompanied by a temporary loss of endocrine balance, and it is not improbable that a similar state of affairs may arise during the period of sexual decline in the male. For this reason I have considered it advisable to examine the interstitial cells of the testis, the suprarenal capsules, and the pituitary in cases of prostatic enlargement. The necessity for examining the interstitial cells of Leydig had, indeed, long been apparent, and remembering the tendency of "prostaties" to exhibit exaggerated sexual desire, the possibility had occurred to me that enlargement and sex hyperaesthesia might both depend on an increase in Leydig cells. That this is not the case has already been shown in the section dealing with changes in the testis. I found that Leydig cells were diminished rather than increased in cases of prostatic enlargement. So far I have not been able to demonstrate any alteration in structure in either the suprarenal or the pituitary, but as the histology of the endocrine glands is notoriously difficult on account of early *post-mortem* changes I would prefer at the present to make no further statement on the subject. The condition of the endocrine glands in cases of prostatic enlargement offers a fruitful field for research, not only by means of histological methods, but still more by an investigation of basal metabolism and a determination of the respiratory quotient.

Racial Distribution of Enlargement.

In the hope that thereby some light might be thrown on its etiology, I have obtained what information I could on the incidence of prostatic enlargement amongst the various races of the world. In trying to arrive at an estimate of its frequency it must always be borne in mind that enlargement is a disease of old age, and that where old men are rare enlargement will be rare also. This undoubtedly explains to some extent the rarity with which prostatic obstruction is encountered amongst certain African races. It also makes the interpretation of hospital statistics difficult, and prevents the giving of anything more than a general impression of the frequency of the condition.

The following summary has been prepared from the answers received to my questionnaire inquiring into the incidence of the condition in the various countries of the world.

India.—Prostatic enlargement is fairly common, but less so than in England. In an out-patients' department dealing with approximately 1,000 new male cases per annum, some 30 cases of prostatic enlargement were seen. The condition is definitely commoner amongst Mohammedans than Hindus. It is found more frequently

amongst the well-to-do than the hospital class. As in other countries where the individual reaches sexual maturity at an early age the onset of symptoms from enlargement is earlier than in England.

Japan.—Prostatic enlargement is very rare. Dr. Matsumoto reports that in the records of the out-patients' department of the special Hospital for Urinary Diseases at the University of Kyoto there is an average of four cases of enlarged prostate per annum, although the total attendances run into several thousands. Professor Hayami, of the same university, has never encountered the condition on the dissecting table. Japanese literature on the subject is very scanty.

China.—Very rare. Dr. Koch, of the Government Hospital at Hong Kong, states that during the last fourteen years no case of enlargement has been seen, although the yearly average of in-patients is 4,000 and of out-patients 25,000. Similarly, in the Canton Hospital records for the years 1915, 1916, and 1919 there are three entries of prostatic enlargement, although during the same period as many as 156 cases of vesical calculi are recorded. During the ten years 1910-1919, 13,761 operations were performed in this hospital, of which 6 were prostatectomies.

Egypt.—Fairly common, but less common than in England. At the Kasr-el-Ainy Hospital, Cairo, there were 17 cases of prostatic enlargement in 1921 out of a total of 8,472 male in-patients. This appears to constitute an average for the last ten years. All except one of these cases were amongst Egyptians. The actual incidence of the trouble is higher than the above figures indicate, as patients do not usually report until urgent symptoms supervene. It appears to be common amongst the well-to-do classes. In Upper Egypt and the Sudan enlargement is much rarer. It is interesting to note that in the same region hypertrophy of the breast in the male is comparatively common.

South Africa.—An inquiry amongst medical men practising amongst natives has elicited the unanimous opinion that enlargement is extremely rare amongst the natives of South Africa. It must, however, be remembered that few natives live beyond the age of 50.

South America.—Common to those of European stock living in large cities. Incidence amongst aborigines unascertained.

North America.—Incidence in white population apparently as great as in England. The majority of American writers agree that the condition is rare amongst the negroes of the States, the only statement to the contrary being made by Matas. C. H. Day estimates the ratio of incidence amongst whites to that amongst negroes to be as 7 to 3. If this is only approximately correct the incidence amongst the negroes of North America would appear to be greater than that for the original African stock from which they came.

Incomplete as this attempt to discover the incidence of prostatic enlargement may be, it is at any rate sufficient to justify the following deductions:

1. That enlargement of the prostate is a condition having a definite distribution that is anthropological rather than geographical in character. Whereas the condition is common in the Circassian race generally, both in Europe and in the New World, it is somewhat less frequently found amongst those of Semitic and Arab stock, and amongst the inhabitants of India. Amongst Mongols and Negroes it is extremely rare.
2. That enlargement can have nothing to do with the causes that have at various times been suggested as determining its incidence—that is, previous attacks of gonorrhoea, sexual excesses, masturbation, etc.—for the races that are more or less immune from enlargement are the very races in which these supposed causes are most in evidence. Generally speaking, enlargement is commoner amongst meat eaters and those leading the sedentary lives of cities than amongst the vegetarians and frugal lovers.

Conclusions.

1. It is impossible to explain enlargement of the prostate by any theory of chronic inflammation alone.
2. Although enlargement may reproduce conditions favourable to the development of a neoplasm, the enlargement itself does not come into the category of true tumours.
3. The condition is in the nature of a fibro-epithelial degeneration which finds its analogy in the female in serocystic disease of the breast.
4. This degeneration may be regarded as an accident occurring during the progress of involution of the genital tract.
5. The cause that determines the onset of the condition is unknown, although it is not improbably connected with a loss of endocrine balance occurring during this period.
6. Prostatic enlargement shows a definite distribution that is anthropological rather than geographical in character. It very rarely occurs amongst Mongolians and Negroes.

My thanks are due to so many for their assistance in providing me with material and facilities for the above research that it is impossible to mention them all specifically by name. I wish, however, to express my special obligation to Professor Reynolds,

I.R.C.V.S., and above all to Sir Frederick Mott, F.R.S., and the authorities of the Maudsley Hospital for allowing me to work in their well-equipped laboratories.

METABOLISM OF CHILDREN UNDERGOING OPEN-AIR TREATMENT, HELIOTHERAPY AND BALNEOTHERAPY.

BY

LEONARD HILL, M.B., AND J. ARGYLL CAMPBELL, F.R.S., M.D., D.Sc.

(FROM THE NATIONAL INSTITUTE FOR MEDICAL RESEARCH, HAMSTEAD.)

With the Co-operation of

SIR HENRY GAUVAIN, M.A., M.D., M.C.

In consideration of the beneficial effect of heliotherapy in the treatment of tuberculosis attention has been turned almost entirely to the influence of the ultra-violet rays, which do not penetrate more than 0.1 mm. (F. E. Barnard), being absorbed by the surface film of the skin; and (perhaps) more justly to the luminous rays, which, in part, penetrate and are absorbed by the blood and deeper tissues. Other factors of great importance must also be taken into account—namely, the effect of the cooling power of the open air on the exposed body in stimulating muscle tone and body metabolism; the effect of breathing cool air with low vapour tension on promoting evaporation from the respiratory membrane,¹ and so enhancing the outflow of secretion from it and the flow of lymph and arterial blood through it; the effect of cool air in promoting evaporation from and flow of lymph through sores and discharging sinuses; the effect of sunshine in promoting such evaporation and flow, and in warming diseased parts exposed to it. In this paper we propose to consider the effect on body metabolism.

In published results² it was shown that body metabolism or heat production of healthy adults was raised by sitting quietly out of doors in the shade for half an hour on an ordinary winter's day, and that the increase was necessary to raise metabolism. We found that the increase was between 15 and 20, as measured by Hill's method, and gave the proper conditions for avoiding shivering for our subjects, who wore the same clothes as indoors.

To continue our observations on the effect of open air, and at the same time to investigate that of heliotherapy on body metabolism, we carried out a number of experiments at Lord Mayor Treloar's Hospital at Alton, and Hayling Island, Hampshire, during the past summer. In the present paper we record these results.

The conditions at this hospital were particularly suitable, our subjects being children with surgical tuberculosis, treated, among other methods, by open air and heliotherapy. After a course of skillful training the children are able to lie naked in the open air for many hours under atmospheric conditions which would soon make an ordinary healthy individual shiver and uncomfortable unless wearing his ordinary clothes. The process by which the children are inured to exposure is a gradual one and takes a longer time in some cases than in others. Sir Henry Gauvain, the medical superintendent, has described the method as employed at Alton.

Methods.

We used the Douglas-Haldane method of indirect calorimetry, following the directions given by Cathcart;³ in this

method, which is recognized to be an accurate one, both O₂ and CO₂ are estimated in the expired air.

The children under observation were of an age—8 to 16 years—of understanding, and met the conditions of experiment willingly. After a few preliminary trials with the mouthpiece, the process of taking a sample of expired air concerned them little. One factor which helped us considerably was that our subjects, being hip or spine cases, were fixed in splints in bed. Movement, except of the head and arms, was practically impossible. We took care to exclude movement of the head and arms for the usual period before taking the sample.

Breakfast was taken at 6 a.m., a glass of milk at 8.30 a.m., dinner at 12 noon, tea at 4 p.m., and supper at 7 p.m. (summer time). In the case of observations made before breakfast, breakfast was taken at 8.30 a.m. Observations after breakfast were made between 10 a.m. and 12 noon; those after dinner between 2 p.m. and 4 p.m.

Records of dry and wet bulb air temperatures, of dry and wet kata-thermometer cooling powers, and of black fur surface temperatures were taken to give indications of the atmospheric conditions under which the observations were made. The last give a measure of the radiant energy of the sun. Records of cheek surface and axillary body temperatures and of pulse rates were also taken. We did not employ subjects who showed an abnormal body temperature. Only one or two of our cases showed a broken skin, and these lesions were sinuses or ulcers of a minor degree.

For comparison, we have used the figures for calories per diem given in Benedict and Talbot's⁴ standards for children of the same weight as ours; these are well known basal standards. Strictly speaking, the only figures of our results that may be compared with these basal standards are those we obtained from our subjects in the post-absorptive state—that is, before breakfast. Nevertheless for comparing one set of our figures with another set of our figures obtained under similar conditions in regard to the taking of food, we have taken the liberty of using these standards, and noted what difference each set of our results showed from the standard for children of the same weight as ours. This seemed to be the best method for comparing our results. We have also calculated the heat production per unit of body surface, using both Du Bois's⁵ and Benedict and Talbot's⁶ formulae for calculating the surface and reaching the same conclusions from the use of each.

Results obtained from Children who had been Treated for many Months with Open Air and Heliotherapy.

Our first experiments were done on children who had been under treatment for many months. Some of them had pigmented very well under the influence of the sun—that is to say, they had not blistered, but bronzed. Others, who did not pigment well, easily blistered, and, not tolerating much exposure to sun, were kept more in the shade. All the children on an ordinary summer's day wore only loin-cloths, and paid no attention to the fact that they were so much exposed to the open air; there was no evidence of shivering.

Sir Henry Gauvain states that the children who do not pigment well are slower in progress. We noted that the children who pigmented well were usually of better weight than those who did not pigment well, but the average difference in metabolism at Alton was negligible after due allowance was made for difference in weight. From this we conclude that heliotherapy was not so much responsible for the rise in metabolism observed as was the open air, since those who pigmented well received much more heliotherapy than those who did not pigment well.

We should like to emphasize here that we were not dealing with the cure of the disease but with the metabolism alone. While many clinicians hold the view that heliotherapy is greatly concerned with the arrest of the disease, the different factors at work have not so far been analysed.

To return to our results: Table I shows the figures obtained from those who pigmented well, and Table II shows the figures from those who did not pigment well. The two sets of figures may be compared. Taking both Table I and Table II together the average increase of our figures before breakfast above the standard figures for the same weight was about 40 per cent., whereas after breakfast and after dinner the average increase over the standard was about 50 per cent. The out-of-door cooling power and its effect on metabolism vary, but we may conclude that the average effect of the hospital food in our observations was not more than 10 per cent. Du Bois found the basal metabolism increased only

TABLE I.—Average Figures for Children who Pigmented Well.

Time and Place.	Age (Years).	Weight in Kilos.		No. of Observations.	Calories per diem.		Percentage Increase of Calories over Standard.
		Found.	Standard*		Found.	Standard.	
Before breakfast.							
At Alton ...	11.5	32.0	32.0	7	1593	1172	36.3

After breakfast.							
At Alton ...	12.0	27.6	35.0	9	1579	1046	50.9
At Hayling ...	11.0	25.4	30.0	19	1464	974	50.3
After dinner.							
At Alton ...	11.3	37.2	31.0	9	1852	1302	42.2
At Hayling ...	11.7	30.9	34.0	21	1670	1108	50.7

* For same age.

† The resting metabolism found during exposure out of doors is calculated per diem. The metabolism is at a lower figure when the child is clothed and in the ward during the night.

‡ For same weight without food.

2 per cent. by a light breakfast (two to three hours after it). We consider that the 40 per cent. increase of our figures above the standard was due to increase of bodily tone by exposure to open air. We have already proved that metabolism of healthy adults wearing ordinary clothes is raised sometimes nearly 40 per cent. by open air apart from heliotherapy.¹

TABLE II.—Average Figures for Children who did not Pigment Well.

Place and Time.	Age (Years).	Weight in Kilos.		No. of Observations.	Calories per diem.		Percentage Increase of Calories over Standard.
		Found.	Standard.		Found.	Standard.	
At Alton.							
Before breakfast	10.3	23.4	27.0	9	1345	948	41.8
After breakfast...	11.7	26.3	33.0	10	1431	1017	40.7
After dinner ...	13.0	29.4	40.0	10	1636	1091	49.5

Some may think that the better conditions of diet, etc., provided in hospital were partly responsible for the increase in the case of these children, but we take it that they were not much better than the conditions for the healthy children from whom Benedict and Talbot obtained their standards. It is not merely a question of provision of food, but of stimulus, by open air exposure, to eat and absorb the food. Other points of argument will be considered in our next experiment.

Results obtained from Children "On Admission" and After the First Three Months of Open Air and Heliotherapy.

Sixteen children, eight boys and eight girls, were employed for observations a few days after admission and again after the first three months of open air and heliotherapy. The girls were above, but the boys were under, normal weight for the same age.

These children were placed in isolation cubicles, which were very well ventilated, the cooling power in these cubicles being much the same as in the shade outside. The children were in bed covered with light bedclothes. As a rule the upper part of the body was covered only by a thin shirt. There seems little doubt that most of them had been much more shut up in their own homes.

As a rule we took four observations on consecutive days from each child whilst in the cubicle a few days after admission, so that they would be accustomed to their new surroundings. After two weeks in the cubicles the children were taken outside in bed and gradually exposed to the open air and sun. Some of them were more able to stand exposure than others at the end of three months' treatment, so that the former were more pigmented than the latter. In any case none of these children were so well adapted to exposure as the children who had been in hospital for some months longer.

Table III shows the average results we obtained "on admission" and "after the first three months of treatment." It will be noted that "on admission" our figures were about 30 per cent. above the standard, and "after three months of treatment" they were about 50 per cent. above the standard, so that there was a 20 per cent. increase in metabolism. These observations were taken after breakfast and after dinner, but we were careful in each case to take the observations "after three months' treatment" at the same time, with regard to meals, as our observations "on admission."

We have already shown that on an average the hospital diet is responsible for an increase in metabolism of 10 per cent., so that our figures become for "on admission" 20 per cent. above the standard, and for "after three months' treatment" 40 per cent. above the standard. We have made full allowance for the children's increase in weight owing to their condition improving, in the hospital, by taking, for comparison, the standards for the different weights of each child observed "on admission" and "after three months' treatment."

TABLE III.—Average Figures showing Effect on Metabolism of Three Months' Treatment.

	Eight Boys, aged 10.4 Years.	Eight Girls, aged 9.5 Years.
Weight in kilos:		
On admission	22.3	25.8
After three months' treatment ...	24.3	27.0
Standard for same age	27.0	24.0
Number of observations:		
On admission	29	37
After three months' treatment ...	30	28
Calories per diem:		
On admission, with food	1183	1270
After three months' treatment, with food	1450	1514
Standard, for same weight on admission, without food	916	916
Standard, for same weight after three months' treatment, without food.	973	975
Percentage increase of calories found over standard:		
On admission	29.1	34.2
After three months' treatment ...	50.2	55.3
Percentage increase in metabolism after three months' treatment	21.1	21.1

It seems at first sight a remarkable result that the children examined in the cubicles "on admission" had a metabolism on an average 20 per cent. above the basal standard. The observations numbered 96 for 22 children. Recently Blunt and others,² using an indirect method of calorimetry, and therefore not a closed chamber, found that the basal metabolism of under-weight children tends to be higher than that of the normal child. In some of our cases this may be the explanation, but many of our children were not under-weight, and those who were under-weight did not by any means give the highest percentage increments. Wright,³ using the same method as we did, has published some figures which indicate that the metabolism of healthy British naval youths in bed and in hammocks is much higher than the basal standards for children in closed chambers. The increase is probably due to the different conditions of atmosphere and clothing under which our observations and the basal standards were obtained.

As already stated, our observations "on admission" were taken in especially well ventilated cubicles, whereas Benedict and Talbot's standards were obtained whilst the child was in a closed chamber. Undoubtedly under our conditions more "tone" would be retained than under Benedict and Talbot's conditions. The temperature inside their chamber was not far from 22° C. to 23° C. The authors⁴ advise that the subject in this chamber should be dressed, including stockings and shoes; in addition a pair of woollen socks should be drawn over the shoes to prevent cold feet. In the cubicles at Alton we observed an average dry bulb temperature of 19.9° C., the figures ranging from 17.4° C. to 22.6° C. We

have shown^{1,2} that body metabolism is not regulated by temperature of the air, but by cooling power—that is, the wind and other factors are concerned as well as the dry bulb temperature.

We must take into account the presence of muscular spasm in some of our cases owing to the disease, but these worst cases did not give the highest figures; and Wright's naval cadets were obviously not ill. We see no reason to assign any great part to psychological influence, since our subjects were isolated and were accustomed to their new surroundings before we made our observations.

It is possible that English children have a somewhat higher basal metabolism. We do not know of any observations that have been done on children of this age in this country in chambers similar to those used by Benedict and Talbot.

Note on Balneotherapy.

In Table I it will be observed that we have given separate figures for Alton and Hayling Island. The Hayling Island percentages are, on the whole, higher than those for Alton. At Hayling Island the children lived in a more exposed position, and had balneotherapy in the sea in addition to open-air treatment and heliotherapy. The period of immersion in the sea varied between half a minute and seven minutes per day during the summer, with a sea temperature of about 60° F. We took samples of expired air for analysis during the immersion, and found that metabolism was between two and three times that of resting metabolism, and, of course, higher if movement—swimming, etc.—were allowed. Sir Henry Garrair states that some children do better under the seaside conditions at Hayling Island than inland at Alton; others do better at Alton than at Hayling Island; others, again, do better if given an occasional change from one place to the other.

In conclusion, we wish to state that the excellent muscular tone and condition of the children who had been treated is sufficient evidence of the high value of the methods employed, and is remarkable when one considers that the children had been fixed in splints in bed for so long a time. It seems likely that this carefully graduated treatment could be applied with success in other conditions involving a long period in bed.

We are indebted to the members of the hospital staffs for much help during this work.

Summary.

1. Observations during the past summer on metabolism of children crippled with surgical tuberculosis and lying fixed in splints in bed and more or less nude, at Lord Mayor Treloar's Hospital, Hampshire, are described. Their metabolism on the average was increased 40 per cent. above the standard, for the same weight, of children confined in a closed calorimeter.

2. After three months' treatment, including graduated exposure to open air and heliotherapy, their metabolism out of doors was 20 per cent. above that in well-ventilated cubicles soon after admission.

3. Children who had been treated for many months showed high metabolism in the out-of-door conditions, those who pigmented well in the sun giving about the same figures as those who did not pigment well, after making allowance for weight. The former gave the better figures for weight.

4. It is considered that the rise in metabolism caused by heliotherapy *per se* is insignificant compared with that caused by exposure to open air. At the same time the value of heliotherapy as a factor towards arrest of the disease is not disputed.

5. Children on admission in well-ventilated cubicles gave results about 20 per cent. higher than basal standards for closed calorimeters. It is considered that the open-air conditions in the former were mainly responsible.

6. Balneotherapy increases metabolism much above the resting level.

7. The bodily tone and general condition of the children under the specially graduated treatment is remarkable when the long period of immobilization in splints in bed is considered. The treatment might be applied with advantage in other cases involving long confinement in bed.

¹ Varying periods of immersion result in corresponding variations in body temperature, and in a ready and controllable degree. We are not conscious of any undesirable side-effects, though the desirability of this factor in treatment.

APPENDIX.

A number of experiments were completed during the past few winter months. On suitable days the children were placed out of doors in the sun, even though the temperature of the air was very low. They were covered up with bed-clothes, only the face and hands being exposed. The days were few on which the children had to be kept indoors during our observations. The table shows the results obtained, the figures being given as percentage increments over the standard basal figures for the same weight. The observations were made about five hours after breakfast and three hours after a glass of milk, so that no more than 10 per cent. should be deducted throughout for the influence of food.

Table showing Percentages above Basal Figures.

	Subject.					
	H.Z.	J.L.	A.H.	H.N.	E.G.*	J.C.*
In Summer, under ordinary conditions of open-air treatment	37	52	45	60	63	52
In Winter:						
Under ordinary conditions of open-air treatment	58	59	73	95	99	73
In warm room at 70° F. ...	—	50	51	73	62	27

* E.G. and J.C. were kept in the warm room at 70° F. for four days and four nights, and for some observations were in the post-absorptive state.

It will be observed that the winter results are, on the whole, a good deal higher than those obtained for last summer. Apart from this general statement, the winter results are not comparable with one another, since some were taken on much colder days than others, as indicated by the cooling power of the atmosphere.

We also imitated Benedict and Talbot's conditions by placing the subjects in a warm room at about 70° F. The results in the warm room should be compared with the winter results under ordinary conditions of treatment, as the former were, as a rule, obtained a couple of hours after the latter. The metabolism was decreased—in some cases markedly—by this process, but on the whole it was still much above the basal standard. We do not think that the disease in itself can explain much, if any, of the difference, but think it probable that the children, owing to open-air treatment, had a higher basal metabolism than those from whom the basal standards were obtained in America, and that only prolonged warm room treatment will bring it down. The Britisher going to the tropics has, at any rate for some time, a higher basal metabolism than the native during waking hours.

THE members of the City Medical Society of Kankakee, Illinois, U.S.A., have been discharging since March, 1921, the duties usually performed by the county and township medical officer with regard to necessitous persons, and recently also those of the medical officer of health for the city. The members of the society are divided into four groups, each of which serves for three months. In each group are practitioners who are competent to do major surgery, as well as specialists in eye, ear, nose, and throat work. The scheme provides that the indigent shall have a choice of medical practitioner, and, according to the *Journal of the American Medical Association*, the service is more competent than could be rendered by an individual medical man; the expense to the community is no greater. The fee the society receives for this work is devoted to maintaining headquarters for the organization and a library, and any surplus which may accrue will be used to provide greater facilities and equipment for all medical practitioners who are members of the organization.

STREPTOCOCCAL INFECTION BY THE NASAL
AND BUCCAL PATHS.*

BY

DANIEL C. EDINGTON, M.D.,

PENRITH.

It is interesting to trace the recognition of the nasal and buccal areas as points of incidence of infection. From 1885 to 1890, in the early days of bacteriology, many varieties of unclassified and unnamed bacteria were demonstrated in sections of decayed teeth and by needle culture from teeth cavities. Later came Hunter, with his researches on pernicious anaemia, which he attributed to absorption from drain infection, septic teeth, or septic mucous membranes connected with teeth, producing a subacute or chronic systemic bacterial infection. Later it was accepted that frequently after an attack of acute tonsillitis there followed in about fourteen days a more or less subacute rheumatism. This pointed to the tonsillar pharyngeal mucous membrane as an area of infective incidence. Then came the recognition of pyorrhoea with its strepto-bacillus and its importance as a possible cause of many diseases, prominently rheumatic diseases. We know of cases of acute streptococcal poisoning from Ludovic angina types, also from septic tonsillar abscesses, sometimes associated with infectious diseases, frequently not; also of cases of septicaemia following tonsillar or turbinal manipulations. We have accessory sinus suppurations due to streptococcal infection, and cases of rheumatic fever sometimes following excision or enucleation of the tonsils too soon after rheumatic tonsillitis. Again, in association with influenza epidemics, at odd times and places we meet with cases of streptococcal pneumonia, primary and secondary, with a high mortality; and, most important of all, a definite recognition and classification has been given within the last few years to the infective endocardial conditions.

The question I wish first to discuss is the path of infection of these various systemic conditions and the prominent part played by the nose, nasopharynx and throat, and the lymphatics and veins associated with these organs.

Paths of Infective Distribution from Nasal, Nasopharyngeal and Buccal Membranes.

Lorrain Smith has strongly emphasized the question of the incidence and distribution of any and all infections; what determines the selective distribution of organisms to any particular organ or organs? We do not know why streptococci from the mouth or nose should select the fibrous thickened cardiac valve-cusps for attack, as in subacute infective endocarditis, or why tuberculous infection in some cases should select the suprarenal glands, ignoring the nearer and larger organs. Rosenow and others in America have recently demonstrated the possibility of duodenal and gastric ulcers, appendicitis and colitis, being due to streptococcal infection from the mouth and teeth. Many of these diseases are possibly merely local craters in a general blood infection.

Venous and Lymphatic Drainage.

The mouth venous drainage is mainly by the pterygoid plexus and facial veins to the internal jugular vein and so into the circulation, and from the tongue directly by lingual veins into the internal jugular vein. There are also connexions with the pharyngeal venous plexus. The teeth venous drainage passes from the inferior and superior alveolar veins into the pterygoid plexus and facial veins and thence to the internal jugular vein. The mouth lymphatics drain to the submaxillary, submental and parotid lymph glands, whose efferents pass to cervical lymph glands. The tongue lymph glands drain from the sides and middle of the dorsum to glands at the carotid bifurcation. The teeth lymph drains to the submaxillary, submental and parotid lymph glands.

The nasal venous drainage is mainly to the pterygoid plexus from the sphenopalatines in the sphenopalatine foramen, also importantly connected with ethmoidal tributaries of the superior ophthalmic veins and tributaries of the angular vein at the bridge of the nose. Infection might pass this way into the orbit or to venous sinuses as the ophthalmic veins enter the cavernous sinus and the angular veins are connected with the anterior end of the superior sagittal sinus. The nasal external lymph vessels pass to parotid and submaxillary lymph glands, and some few to the superficial

cervical lymph glands. The muco-periosteum anteriorly drains externally to the submaxillary glands and posteriorly to the superior deep cervical glands and the lateral retropharyngeal glands. The nasopharyngeal venous drainage is mainly sphenopalatine, etc., into the pharyngeal plexus and thence to the internal jugular vein. The nasal lymphatic drainage is to superior deep cervical lymph glands, and some to the retropharyngeal lymph glands—hence arise retropharyngeal abscesses.

The palatine tonsil lymph vessels pierce the pharyngeal wall laterally and end in glands on the internal jugular vein below the posterior belly of the digastric at the level of the angle of the jaw. The venous connexion of these regions with the meninges is brought about by the drainage into the venous pterygoid plexus, which receives (1) emissary veins through the foramen ovale from the cavernous sinus, and (2) connexions from the inferior ophthalmic vein through the inferior orbital fissure. A circle is thus formed by the pterygoid plexus, nasal vein and other connexions, with ophthalmic vein and the superior longitudinal sinus, the ophthalmic veins entering the cavernous sinus and emissary veins passing to the pterygoid plexus.

Bacteriology of the Nasal, Nasopharyngeal and Buccal Mucous Membranes.

Broadly speaking, the nasal healthy secretion is non-bacterial. The sinuses if healthy are sterile, the vestibule is usually bacterial and sometimes pathogenic, containing varieties of staphylococci and micrococci and streptococci. In 26 cases of healthy mucous membrane, Lewis and Turner found streptococci in 6, staphylococci in 13, and pneumococci in 4. In an unhealthy nose and nasopharynx the three prominent bacteria are streptococci, staphylococci and pneumococci in varying strains, together with at times the influenza bacillus and certain putrefactions and coryzal bacilli, etc. All nasal inflammations are due to pathogenic organisms, either virulent, or capable, if avirulent, of being stimulated to virulence by chills, traumatism or debility; hence the onset of acute sinus abscesses after coryzal colds and sore nose conditions in extreme asthenia during pulmonary tuberculosis, typhoid fever, etc.

The nasopharyngeal and mouth varieties of organisms are much the same as the nasal, and are derived from food, water, and air. Teeth show organisms on the surface of dentine, and also in the deeper tissues. Mouth acids are always a result of bacterial action; they decalcify teeth, and so start caries; thus in deep dental caries we find streptococcal varieties along with the *Bacillus necrodentalis*, etc. There are many varieties of bacteria in the mouth—fermentative, pathogenic, etc. Accessory sinuses are sterile if healthy. If unhealthy, they usually show streptococci, staphylococci, and pneumococci, with catarrhal bacteria, and sometimes the *Bacillus coli communis*; in other words, the same varieties of bacteria as are found in the buccal and nasal cavities. In a hundred cases investigated (Lewis and Turner) 75 per cent. showed streptococci, 74 per cent. showed pneumococci, and 70 per cent. staphylococci, with occasional *Bacillus diphtheriae* and *Bacillus influenzae*, etc. These details are from the research works of Lewis and Turner, Reynolds, Fraser, Ritchie, etc.

Antral suppurations are 58 per cent. nasal in origin, 30 per cent. of these beginning by influenza attacks; 14 per cent. only are coryzal in origin, 37 per cent. are due to infection from teeth, and 2 per cent. are traumatic (Lewis and Turner). Streptococci are more numerous in chronic than in acute sinus suppurations, in the proportion of 80 per cent. to 60 per cent. Thus from nasal, nasopharyngeal and buccal cavities the above pyogenic organisms, together with Pfeiffer's bacillus, pneumococci, meningococci, and tubercle bacilli, are capable of passing to the brain, probably by venous channels, and producing such diseases as suppurative, influenzal, pneumococcal, and epidemic cerebro-spinal meningitis, also probably acute poliomyelitis and tuberculous meningitis, tuberculous and septic cervical glands; and, by way of the Eustachian tube, middle-ear disease and mastoid infection; while in the general system by absorption through the lymphatic channels of mouth and nose and nasopharynx, pneumonia, pernicious and septic anaemias, infective endocardial conditions, rheumatoid arthritis, etc., may be established. The main paths of infection are the lymphatic channels, but probably venous to the meninges. Broadly speaking, the same infective chief organisms—namely, the streptococci, staphylococci and pneumococci—are found in the nasal, pharyngeal and mouth mucous membranes, and by way of the Eustachian tube the

* Presidential address, Border Counties Branch, British Medical Association, September 23rd, 1921.

same organisms may infect the middle ear and the mastoid cells. They may infect the brain cavity, as previously described, but probably only by venous routes, as only effluent lymphatics from the brain have been demonstrated.

It is not necessary to describe cases such as suppurative meningitis, middle-ear disease, mastoid abscess, Ludwigian angina types, acute septic tonsillitis, or acute accessory sinus suppurations. These are all direct and acute and call for direct surgical treatment chiefly. Let me now rather briefly describe the course of streptococcal pneumonia, subacute emicisms (Addisonian) anaemia, and the more indirect, subacute and giving very unsatisfactory results by all known treatment up to date.

Streptococcal Pneumonia.

In what may be called primary acute streptococcal pneumonia there is usually severe deep central pulmonary pain referred to the deep subclavicular region. Distress is severe, with a general early toxic appearance, a rapid pulse of 120 or more which remains high though the temperature may be remittent, while delirium is frequently early. Respiration from the first day runs to 30 and upwards, sputum is not typically rusty and viscid, and dullness is only comparative, with marked diminished breath sounds and much confused moist crepitations. If these cases survive the first five days they often fail to complete hepatization with its dry tubular breathing, but they continue more bronchopneumonic with increasing myocardial weakness, with frequently progressive infection to other parts of the lung, such as centre to apex to base, which in a week or ten days later may pass to the other lung.

The usual termination in this migratory form of pneumonia is death. This was the type of pneumonia I first saw in 1893, in an epidemic of influenza which broke out in the Caledonia training ship at Queensferry. The first symptoms in most cases were followed in twelve hours by delirium, and often death inside of two days. The same type of pneumonia characterized the devastating influenza epidemic of 1918-19. In the post-mortem examinations of the 1893 cases we usually found numerous areas of what would be best described as bronchopneumonia, but sometimes both lobar and lobular, with liquid purulent centres from which we cultivated streptococci and other unclassified organisms. Secondary streptococcal pneumonia is well known in regard to septic surgical and puerperal cases. The Johns Hopkins reports on epidemic pneumonia in the American army in 1918 state that it was of the above type, all cases showing streptococci and some also the influenza bacillus (30 per cent. only).

Let me now describe a few cases showing the unexplained selective distribution of the streptococcus in the general system.

Subacute Infective Endocarditis.

This is found developing in endocardial lesions of long standing, especially in incompetency of the aortic or pulmonary valves. The disease, first described by Osler in 1908 and Horder in 1909, was thoroughly detailed by Cotton in the BRITISH MEDICAL JOURNAL of December 4th, 1920, and again described and discussed, chiefly by Horder and Libman, at the British Medical Association meeting of 1920. It is a remarkable fact that rheumatism and syphilis attack healthy heart valves, whereas subacute infective endocarditis only attacks primarily diseased valves of rheumatic causation; hence it is suggested that we should endeavour to prevent this dread ailment by specially immunizing rheumatic valvular diseased patients against the *Streptococcus anhaemolyticus*, the main cause of the disease. This is advised by Horder and Libman. It affects patients from 15 to 50 years of age. It grafts on the fibrous lesions in the cusps, sometimes on the lesions on septum or edges of a patent ductus, and thus sometimes you have little or no murmur to guide you. It is well marked but subacute and insidious in its early advance, so much so that many cases carry on their ordinary work as before for several months of an illness ranging from about six to eighteen months.

A man aged 49 at the age of 7 had an obscure rheumatic attack of seven weeks' duration; I sent him to Sir James Mackenzie in 1908 suffering from pulmonary valve incompetency probably due to the illness at 7 years of age. He stated that in April, 1920, he began to have what he thought were recurrent malarial rigors, having had malaria several times in South America, between 1909 and 1915. He consulted no one, but went out to the Argentine on business, as he did nearly from July to November. He noticed that he was losing weight in September, and also noted a rise of temperature

at night. In the early part of October he had a very bad epistaxis, so severe that he went to the British Hospital, where his nose was plugged. He had blood examinations for malaria, syphilis, tubercle, etc.; no organisms were found, but no blood cultures were made. He was advised to return to London at once owing to the great heat. He arrived in London on December 8th, and came under the care of Dr. Robert Hutchison. His nose was canterized at once. Blood cultures were then taken, and all of them showed *Streptococcus anhaemolyticus*. There was marked loss of flesh; the heart showed a loud basal murmur, there was oedema of the legs, intermittent septic temperature, pulse rate 106 to 120, unequal, irregular and soft; a large palpable spleen and petechial crops on the upper arms, forearms, legs, and neck, venous engorgement of the neck, sweating and variable pains in the legs, back, and joints. On arriving in Cumberland on December 33th I found, additional to these, slight clubbed fingers, with painful trochanters. The heart was enlarged fully two inches beyond the nipple line, with a diffuse heaving impulse. The spleen margin was three inches below the ribs. There was marked septic twitching of the muscles of fingers and toes. The urine showed blood cells with hyaline and granular casts. The urine was also deficient, with albumin, but only a slight trace; his complexion was chlorotic, with pink malar patches. He showed rapid progressive emaciation, very fickle digestion, constipation, and a moist middle furred tongue.

I got Professor Gulland to see him, and we again examined his blood, which now revealed no organisms. By blood count the red corpuscles were 2,800,000, and the haemoglobin 55 per cent.; the colour index was 0.9; white corpuscles gave 3,300; there was a definite glycogen reaction, septic proof. The differential count of the white corpuscles gave: Small lymphocytes 11.3, large lymphocytes 1.7, polymorphs 56, and eosinophils 0.3 per cent. There was only a slight polikilocytosis, but marked rouleaux formation. The case steadily got worse with frequently recurring emboli to the kidneys, brain, lung, and spleen. He died from gradual exhaustion by toxæmia on February 3rd, 1921. I would reckon his full term of illness at about ten months.

The curious points to note were that his cardiac murmur never appreciably altered, and that petechiae came in frequently increasing crops; the embolic disturbance of the kidneys gradually lessened the urine, but did not markedly increase the albumin. I had no post-mortem examination, but these cases usually show recent vegetations, soft and friable, grafted on the cusp regions and the septal wall—hence the emboli—a large spleen with infarcts, swollen and soft, slight nephritis of the parenchymatous type, with destroyed glomeruli and many infarcts; the lungs are usually oedematous at bases, the streptococci usually numerous in the soft cusp vegetations, but sometimes are shut in. The main early symptoms to look for are: Gross valvular disease of the cardiac valves, pallor, enlarged spleen, and clubbing of the finger-tips; some pyrexia—aortic regurgitant cases show it most, mitral disease alone rarely shows it. There is a marked increase in the incidence of this disease.

Pernicious Anaemia.

In pernicious (Addisonian) anaemia we have a systemic infection characterized by intense haemolysis with alteration in size and shape of the red corpuscles; chlorotic appearance, no emaciation, no temperature variations unless in some post-puerperal and post-traumatic cases. Under arsenical treatment we get frequent recoveries, with the reds increasing from as low as 30 per cent., and haemoglobin from about 30 per cent., to nearly normal, only to be followed by relapses again and again, until sickness and diarrhoea, indicating intense infection of the gastric and intestinal mucosa, develop. This, unless checked by serum or vaccine treatment, rapidly produces death, accelerated by myocardial weakness.

Rheumatoid Arthritis.

In rheumatoid arthritis, or more correctly, peri-arthritis, we again have a systemic infection with joint swellings, progressive, variable and painful. It is usually primarily associated with agencies which lower the general health, hence we must remember to raise this in conjunction with other treatment. Of course we again wonder why the causative bacteria in the general infection select the joint structure as their principal area of activity.

TREATMENT.

- (a) General to all. Inasmuch as all these nasal, antral, buccal, and nasopharyngeal infections are due to unhealthy mucous membranes, etc., the first treatment, if at all possible, should be to eradicate all possible unhealthy nasal conditions—sinus polypi or suppurations, adenoids, tonsils, and teeth, not forgetting septic or tartared plates, but I must advocate conservatism as to teeth.
- (b) In streptococcal pneumonia. In addition to usual hygiene, nourishment, stimulants, medicines, etc., anti-

END-RESULTS OF SANATORIUM TREATMENT OF TUBERCULOSIS.

THE BRITISH MEDICAL JOURNAL

streptococcal polyvalent serum may help; it will certainly do no harm. Stock vaccines are dangerous, and are not held to be sound practice. If an autogenous vaccine can be prepared in very small initial doses, good results may occasionally be got, but it should be carefully used.

(c) In infective subacute endocarditis. In addition to hygiene, nourishment and stimulants, the only treatment with any chance of success seems to be a vaccine (antigenous) or horse serum; antistreptococcal and similar vaccines are useless. Even vaccines show no record of value. Horder and Libman's suggestion to adopt preventive measures in all cases of cardiac lesions of inefficiency by immunizing patients with vaccines of *Streptococcus anhaemolyticus* (or *viridans*) is sound, and the only hope so far.

(d) In rheumatoid arthritis. Much can be done by steady perseverance in raising the general health by diet, clothing, exercise, and climate. Gnaiaeol carbonate, salol, and quinine salicylate help to eliminate the rheumatoid poison. The urine odour is some guide to this elimination. Iron as iodide and Radium, in waters, promises good results. The thermal treatments have their partial successes, but vaccines are giving more hopeful results on autogenous lines, being prepared from cultures from the teeth, throat, faeces, or urino. Phylacogens prepared from rhonchitic streptococci, etc., I have had experience of, but cannot speak of any success. The disease may be due to several infections; if you can find the definite organism, or organisms, autogenous vaccines would possibly do well.

In conclusion, it is evident that we know very little as to the incidence, varying virulence, and selective distribution of pathogenic and pyogenic bacteria. There is a great field of research open to the collaboration of anatomist, bacteriologist, pathologist and dental surgeon. We in this Border Counties area miss much of the clinical picture in difficult and obscure cases through want of a local pathological department. As to treatment, we must have confidence in future research, so that our treatment may become less empirical and general, and more scientific and accurate.

Dr. Bardswell's Class I included only 25 per cent. or less of the total number of applicants, but his definition of this group is limitation of physical signs to the apex of one or both lungs, and the apex is considered as that part accessible to examination in the supraclavicular and suprascapular fossae. We quite agree with this restriction for Class I cases, but in the present communication that class includes cases whose physical signs denoted the involvement of an area of lung not exceeding that of one lobe, provided that severe constitutional symptoms and complications were absent.

In regard to ultimate results according to classification on admission to the sanatorium, Dr. Bardswell also emphasizes the great importance of the presence or absence of tubercle bacilli in the sputum. We are unable to make this distinction with our cases. In an immense majority the tubercle bacillus was demonstrated in the sputum; in the remainder we only concerned ourselves to obtain other unequivocal evidence that the patient was affected with tuberculosis of the lung. The next table shows the different results according to the patient's classification on admission:

Class	Living.	Dead.
Class I	1118	724 = 64.7%
Class II	801	274 = 34.2%
Class III	841	127 = 15.0%

If, therefore, we confine ourselves to the consideration of the more favourable class of applicants for treatment, instead of a mortality of 59.2 per cent. we get a mortality of 35.2 per cent. for the nineteen years. It is interesting to contrast these figures with those of Dr. Bardswell. His first class were, as we have seen, more strictly selected and their mortality was about 30 per cent., but his period embraced only four years. The excessive mortality which occurs during the first few years after discharge from the sanatorium is a point to which we shall refer shortly. The real crux of the matter, however, is the durability of the restorations of health obtained by sanatorium treatment. The next table gives the percentage of our patients now known to be living and to have died, arranged in their classes and according to the year of their discharge from sanatorium. We would repeat that our Class I was too broad and included a number of cases that we would now place in Class II.

THE END-RESULTS OF SANATORIUM TREATMENT OF TUBERCULOSIS:

A RECORD OF SEVENTEEN YEARS' SANATORIUM WORK.
BY
F. W. BURTON-FANNING, M.D.CAMB., F.R.C.P.,
SOBARY PHYSICIAN TO THE NORFOLK AND NORWICH HOSPITAL, KELLING
SANATORIUM, AND STANNINGHALL TUBERCULOSIS COLONY;
AND
W. J. FANNING, B.A.OXON., M.R.C.S., L.R.C.P.,
LATE RESIDENT MEDICAL OFFICER, KELLING SANATORIUM.

The results of sanatorium treatment of patients from the industrial classes have recently been the subject of a good deal of criticism. We propose to publish figures setting forth up to date what has happened to patients admitted to Kelling Sanatorium between 1903 and 1919, and to let these figures speak for themselves. One of us (W. J. F.) has devoted a great deal of time to keeping in touch by continual visits and letters with all our old patients. The only claim we make for this publication is that our patients have perhaps been followed up more closely than is practicable in larger cities, or with more shifting rural populations.

Between 1903 and 1919 sanatorium treatment was given to 3,220 patients. Of this number 460 have been lost sight of, so there remain for consideration 2,760 patients, whose fate at the end of 1921 is here given:

Treated at sanatorium from 1903 to 1919	2760
Living in 1921	1125 = 40.7%
Dead	1635 = 59.2%

Our patients on admission were classed as follows:

Class I	1118 = 42.3 per cent.
Class II	801 = 29.0 "
Class III	841 = 30.4 "

Before comparing these figures with those published by Dr. Noel Bardswell in the November issue of *Tubercle*, and in his memorandum to the London Insurance Committee, we must explain that we have been obliged to adhere to our original classification.

Percentage Discharged.

Years.	Class I.		Class II.		Class III.	
	Living.	Dead.	Living.	Dead.	Living.	Dead.
1903-1905	41.0	55.0	24.0	86.0	4.3	55.7
1905-1908	51.5	45.5	20.2	73.8	8.8	51.2
1909-1911	56.8	43.2	18.5	81.5	8.4	91.6
1912-1914	58.0	42.0	36.5	63.5	14.4	85.6
1915-1917	61.7	38.3	43.9	56.1	21.3	78.7

Of our Class I patients who left the sanatorium between 1903 and 1908, so long ago as thirteen to nineteen years, about one-half are, therefore, still alive. The crucial period is the first four or five years after treatment, and of those who survive this time a large proportion maintain their ascendancy over the malady for an indefinite number of years. This point is forcibly brought out by the next table, which gives the percentages of deaths occurring in five-year periods subsequent to discharge from the sanatorium. Of those that died, death occurred as follows:

Within 1 year	in 6.0 per cent.
Within 1 to 5 years	in 57.6 "
Within 5 to 10	in 23.0 "
Within 10 to 15	in 9.2 "
Within 15 to 20	in 2.9 "

Of all the patients who died after receiving sanatorium treatment, the average length of time between the appearance of the first definite symptom and death was just over five years. Publications which dwell on the number of deaths which occur within a few years of leaving the sanatorium give, in our opinion, an unnecessarily gloomy aspect of the story.

* This classification is that adopted by the London County Council with Department after consultation with the Tuberculosis of the Ministry of Health.

The immediate general improvement and the definite control of important symptoms brought about by sanatorium treatment are not called in question. We are concerned, however, about the proportion of patients who relapse soon after resuming their ordinary modes of life. In our conflict with consumption the part played by the sanatorium must, in our existing state of knowledge, be considered satisfactory, but the treatment needs to be commenced earlier and inhaled differently. The two directions in which reforms must be made for the purpose of securing more lasting recoveries are those of earlier diagnosis and better organized after care. The advantage of placing the patient under treatment at an early stage of the malady is testified to by the records of all sanatoriums. Our first class embraced numbers of patients whose signs were reproachfully obvious and extensive, and yet about half of them have lived for fifteen years or more, mostly able to do some kind of work.

When we appreciate the supreme importance of early diagnosis the classification of cases of pulmonary tuberculosis deserves much consideration. We welcome Dr. Bardswell's proposal as marking a distinct advance in what we should aim at, for classification is used not only to provide convenient headings for the grouping of cases. His Class I, as defined above, represents a stage of the disease beyond which it should be our aim to let no patient go before he is caught and sent to a sanatorium. Dr. Bardswell's wide experience in connexion with the London Insurance Committee is that only 25 per cent. of applicants for treatment are Class I cases. In a communication we made to the *BRITISH MEDICAL JOURNAL* (August 24th, 1912, p. 409) concerning over 1,000 patients, we stated that eighteen months was the average time allowed to elapse between the first obvious manifestation of the malady and the application for sanatorium treatment.

There has certainly been improvement in this all-important direction of earlier diagnosis and treatment. The increasing numbers of expert tuberculosis officers who are at the service of the practitioner in the search for early cases must bear fruit. It was a great move when facilities were made for getting the sputum of any person examined, and as more and more advantage is taken of the public laboratory the practitioner will detect a larger proportion of his consumptive patients in their early stages. Pulmonary tuberculosis should be thought of whenever a cough cannot be otherwise satisfactorily accounted for. We are sure that a number of febrile illnesses of obscure nature owe their origin to tuberculosis. The systematic observation of the temperature in the latter part of the day is now made easier, thanks to the larger number of visiting nurses. A slight degree of fever in the afternoon for day after day, with no symptom perhaps beyond a little tiredness or loss of weight, is very suggestive of tuberculosis. Supposing there is no sputum and the diagnosis cannot be clinched by an examination of that for the bacillus, there is now radiology to be appealed to. In the hands of an expert the evidence of an x-ray examination of the chest may in a large proportion of cases be accepted as proving or disproving tuberculosis. We are certain from our experience that in every centre x-ray examination should be available for the diagnosis of doubtful cases.

A history of certain previous illnesses may arouse the suspicion of existing pulmonary tuberculosis. It is increasingly realized that pleurisy in the absence of pneumonia, rheumatism, septicaemia, or nephritis, must be regarded as tuberculous. Every patient who has had tuberculous pleurisy should be given a course of sanatorium treatment with a view to preventing the subsequent possible involvement of the lungs. In our cases of pulmonary tuberculosis there was a definite history of antecedent pleurisy, which had been apparently recovered from, in no fewer than 22.4 per cent. Undoubtedly to this number might be added others who had suffered from unrecognized or forgotten pleurisy. According to some observers, 40 per cent. of patients who have had primary pleurisy eventually develop pulmonary tuberculosis. There are good grounds, therefore, for giving all these patients the advantage of a precautionary course of sanatorium treatment.

It is contended by some writers nowadays that certain tuberculous manifestations have the effect of rendering the individual immune to pulmonary tuberculosis. Glandular affection, for instance, is stated by some to be always of bovine type, and to protect from lung disease. But of our patients with pulmonary tuberculosis 4 per cent. had previously suffered from glandular abscesses, and our strong impression is that this understates the frequency of the association. In hospital and in private practice one of us (F. W. B. F.)

has seen too many cases of pulmonary disease supervening on tuberculosis of glands to be ascribed to coincidence. In some of these the pulmonary tuberculosis has been of acute type, and it has been difficult to resist the suggestion that surgical interference with the glands or their treatment by tuberculin had stirred up the trouble.

Just under 3 per cent. of our sanatorium patients had previously suffered from tuberculous disease of bones or joints. We think that this by no means represents the actual frequency of tuberculosis of lungs and of bones in the same patient. Surgical tuberculosis is excluded from the sanatorium, but amongst hospital patients it is not uncommon to find combined disease of lungs, bones, joints, and other parts. There is a well recognized form of tuberculosis in which one or both pleurae are apt to be affected with the peritoneum, and at the present time there is a patient in the Norwich Hospital suffering from tuberculous peritonitis and double tuberculous pleurisy from whom tuberculous glands had been recently removed.

Fistula in ano had occurred in only 0.5 per cent. of our sanatorium patients previous to their lung trouble, but it is, of course, more common as a subsequent event. Tuberculous disease of the eye, of the epididymis, and of the Fallopian tube were mentioned in the past histories of a still smaller proportion of our patients. It should be unnecessary nowadays to insist that haemoptysis of any amount approaching a teaspoonful, and without other obvious explanation, is to be taken as evidence of pulmonary tuberculosis, but fatal mistakes are still made about this. In a number of cases pulmonary tuberculosis is said to have followed some other malady. Influenza is given as a particularly frequent precursor, but proof of the exact nature of the illness is difficult to obtain. We would lay more stress on the point that in the light of after events tuberculosis is the possible explanation of many attacks of fever which at the time cannot be diagnosed without the assistance of the specialist in x rays or in bacteriology, and perhaps even their evidence may be inconclusive.

A most fruitful field for the activity of the tuberculosis officer lies in his detection of the earliest cases by the inspection of so-called "contacts." To digress, we think that the use of this word is the begging of an important question. We are not convinced that the main cause of tuberculosis is the infection of the infant or child with the tubercle bacillus from a patient. Without attempting to present the arguments on this point, we would only say that from an unbiased inquiry into the histories of our patients, we thought there was evidence of case-to-case infection of an adult in a very few instances only. In at least 50 per cent. of our cases there was a history of tuberculosis in a parent or brother or sister. According to some writers, these were instances not of heredity, but of infection. How do we explain on this theory the commonly observed fact that one brother or sister after another in a family develops tuberculosis, though neither parent has ever shown any symptom of the disease and though the children for many years had occupied different homes. Again, it is not exceedingly rare to trace the supposed hereditary susceptibility to a parent whose tuberculosis declared itself in disease of bone, joint, or abdomen, where no obvious diffusion of the bacillus took place. Whichever doctrine we adopt we shall agree that the existence of tuberculosis in a relation or the history of certain previous illnesses in the individual would be grounds for looking at him with increased suspicion.

The second direction in which we must aim at improvement is the after-care of our patients. In regard to this the one essential point, according to our experience, is securing for all ex-sanatorium patients continuous supervision by an expert. However thoroughly the patient has been instructed in after-care at the sanatorium, a small proportion only show themselves able to follow the precepts. So manifest an indication of trouble as persistent rise in temperature the patient may have noted but may elect to disregard, or more probably the ex-patient has broken the thermometer, or anyhow has not kept the enjoined watch on his temperature. There are numberless other points which indicate whether or not the consumptive is holding his ground, but the trained eye is needed to appreciate them.

It is only at a sanatorium that the real importance of attention to minute details is grasped, and the advantage of having ex-sanatorium patients under the continued observation of a nurse or doctor who has had this training is obvious. The generally accepted rules of sanatorium treatment have been strictly followed by us, and continued experience has led

to little modification. From the first the patient's exercise took the form of useful work. For more than a year tuberculin was given systematically to a certain group of the patients, but we were not favourably impressed by it.

There has been a farm colony on a small scale in Norfolk for the last eighteen months, and the experience gained there has been most instructive. Generally speaking, the way in which the men's healths have been maintained, or more commonly improved, while they followed some useful occupation, has been highly encouraging. Some of the colonists came to us with the sputum already free from tubercle bacilli, and with signs of only past mischief. With only one or two exceptions these men have gone steadily forwards, and under the conditions of healthy housing, of good feeding, and of regulated work have required little attention. But the men with bacilli still present, and with physical signs placing them perhaps in Class II, have had to be watched more carefully. Even of them the majority have done surprisingly well. At the same time a week seldom passes without one of the colonists being pulled up with the threat of a smaller or greater set-back. Apart from elevation of temperature from increased frequency of pulse or from loss of weight, the jealous eye of the nurse notices loss of appetite or some other indication of lowered health. When this man is examined it may often be found that, sure enough, an extension of his disease has occurred.

Tuberculosis in all its phases is characterized by a broken course with ups and downs, and success in its management depends on any tendency to relapse being immediately detected and properly dealt with. This essential requirement in the after-care of the ex-sanatorium patient seems to us to be best met by the colony scheme. For the man whose tuberculosis has become arrested it is not of supreme importance whether his employment be out of doors or indoors. Of course it is an advantage if he can spend twenty-four hours each day in the fresh air, but it is of more importance to provide that the number of hours and the arduousness of the work be strictly regulated according to the man's ascertained capability.

Some years ago we got out figures for the purpose of comparing the after-results in our ex-sanatorium patients, according to their resumption of an indoor occupation, or to their resumption of an outdoor occupation, or to their changing from indoor to outdoor work. Our statistics showed, however, no striking differences among the three groups. We know that there are many factors to be taken into consideration, such as the healthiness or the reverse of the workroom, the home conditions, the amount of the earnings, and the consequent sufficiency or scarcity of good food, and chiefly whether or not the individuals are worked beyond their strength. Our agricultural labourers, for instance, have not yielded good after-results. Their working hours are spent in the open air, but we know that their toil is arduous, that they are often badly housed, and have been badly fed. On the other hand, the few master farmers who have passed through the sanatorium have mostly continued to do well. Presumably they were able to choose their kind and amount of work, and, of course, they were able to live well.

While indoor work as such is not necessarily harmful, so long as it is not too strenuous, there is information in regard to certain industries which marks them as unfavourable for the ex-sanatorium patient. In Norwich, for example, the clerk of the City Insurance Committee finds that, of 439 men applying for sanatorium benefit, 33.5 per cent. were working in boot factories, and that of 297 women 20.2 per cent. were thus employed. Our sanatorium patients who were forced by circumstances to return to the boot factories have done no better than we should have expected. They are unfitted to take their places beside able-bodied men and to work full time at top speed and perhaps under unhealthy conditions. The experience at Papworth and elsewhere shows, however, that the consumptive man can do remunerative work in the model factory, so long as his exertions are adjusted to his physical powers.

Dr. F. Stanley Tinker suggests the institution of municipal workshops, the men going backwards and forwards from their homes, and working under medical supervision. There may be other solutions of the problem, but we are convinced that for the first five years at least the patient with pulmonary tuberculosis should be kept under close and expert supervision. Such work should be allowed as is found to be compatible with the retention of his ascendancy over the disease. He must be relieved of anxiety about the maintenance

of himself and his dependants, his housing must be seen to, and there must be no difficulty in securing for him return to the sanatorium from time to time if his malady reasserts itself. The difficulty of such provision is, of course, the financial one, but unless this difficulty is overcome part of the expenditure on sanatoriums is thrown away. We know that it is possible not only to prolong the lives of these men, but to make them useful members of the community.

HAEMORRHAGIC COLITIS.

BY

J. W. GEARY GRANT, F.R.C.S. Eng.,

SENIOR ASSISTANT SURGEON, KING EDWARD VII HOSPITAL, AND CHIEF ASSISTANT IN THE SURGICAL UNIT, WELSH NATIONAL SCHOOL OF MEDICINE.

THE following two cases, which, in view of the fact that haemorrhage and the resulting severe anaemia were the leading symptoms, I have ventured to term "haemorrhagic colitis," were in the King Edward VII Hospital about the same time under the care of Dr. Mitchell Stevens, to whose courtesy and to that of Mr. Cornelius Griffiths, who operated on the first case, I am indebted for permission to give this account.

CASE I.

The patient, a housemaid aged 37, stated that for fourteen days she had passed a quantity of blood and mucus in the motions, which averaged five a day. She had had an attack of "dysentery" at Regina, Canada, in 1917, and two similar attacks subsequently. When examined on October 26th, 1920, the temperature was normal. The faeces contained blood, mucus, and pus cells, and *B. coli*. An autogenous vaccine was prepared and administered. At Dr. Mitchell Stevens's request I examined her with the sigmoidoscope, but was unable to get the instrument past the pelvic brim. This was largely owing to the continual flow of blood which obscured the view. The pelvic colon had a granular appearance, and in the upper part there were numerous papillary elevations, the mucous membrane bleeding at the slightest touch. No definite ulcers were seen, but the appearance at the upper part of the pelvic colon suggested carcinoma to me.

On November 28th, 1920, Mr. Cornelius Griffiths opened the abdomen by a median subumbilical incision and drew out the iliac colon which was found to be thickened. A portion of the wall was removed for examination and reported to be haemangiomas. There was not, however, any localized growth but a diffuse thickening of the mucous membrane. A faecal fistula was established. For a month the temperature was irregular, averaging 100° to 101°. Blood and pus passed from the colostomy opening and from the anus, and staphylococci were found in the urine. The Wassermann reaction was negative.

On January 14th, 1921, Mr. Griffiths closed the fistula, and in May she was discharged to a convalescent home, all symptoms having cleared up.

CASE II.

This patient, a clerk aged 21, was admitted under the care of Dr. Mitchell Stevens on January 17th, 1921. He stated that for a month before admission he had passed large quantities of blood from the anus, and that he had passed blood also in small quantities for eighteen months previously; he suffered no pain. He had had no previous illnesses, lived in a mining district, and had not been abroad. The rectum was washed out, and the returned fluid contained blood, pus and mucus. On January 20th, at Dr. Mitchell Stevens's request, I passed a sigmoidoscope, but I could not get it past the angulation at the pelvic brim. The appearance was almost exactly the same as in the previous case. There was a continual flow of blood from the granular and friable mucous membrane of the pelvic colon. He was extremely anaemic and emaciated, and Dr. Mitchell Stevens felt that immediate surgical intervention was needed; the opinion we formed was that he probably had a polypus or multiple adenomata in the colon.

On January 26th, 1921, I opened the abdomen by a median subumbilical incision and drew out the iliac colon. Its wall was thickened and firm; the para-colic lymph glands were enlarged and two were removed for examination. A portion of the wall of the colon was also removed, and the report on this was that it showed a haemangiomatic condition of the mucous membrane, and the glands showed simple inflammatory hyperplasia. I passed a sigmoidoscope as far as the splenic flexure. The mucous membrane simply presented a granular appearance and intense engorgement and bled at a touch. There was no ulceration. As his condition was very bad, I fixed the loop of iliac colon in the wound and established a colostomy with a good spur. He was very collapsed after the operation, but with rectal saline and glucose colostomy discharged pus and mucus freely, with small amounts of blood. It was washed out with saline and with collargol, and horse serum and calcium lactate were administered.

A blood examination on February 2nd showed haemoglobin 65 per cent.; red blood cells, 3,640,000; white cells, 16,000; the cytes 10 per cent., large lymphocytes 76 per cent., small lymphocytes, myelocytes 6 per cent., eosinophils 3 per cent.

On March 16th a blood examination gave the following: Haemoglobin 55 per cent.; red blood cells, 3,250,000; white cells, 8,000; polymorphs 54 per cent., small lymphocytes 44 per cent., large lymphocytes 2 per cent.

The first count showed a high-grade secondary anaemia with a moderate leucocytosis, probably a post-haemorrhagic one; the second, with a higher anaemia, appeared to show a relative lymphocytosis.

Washings from the rectum yielded a thick deposit of pus; epithelial and connective tissue cells were obtained, and a few *Entamoeba coli*.

From a swab of the rectal mucus *B. pyocyaneus* was obtained in almost pure culture, and a vaccine of this was administered. Although *Entamoeba coli* is now generally held to be innocuous, yet, as some authorities hold that all intestinal amoebae are potentially pathological, he was placed on Fowler's solution by Dr. Mitchell Stevens.

The amounts of blood passed were quite small, but as the anaemia was increasing and he appeared to be steadily going downhill, with Dr. Mitchell Stevens's permission I decided to perform appendicostomy with a view to securing a thorough flushing of the whole colon, and this I did on March 16th, although his condition appeared so bad that my house-surgeon did not expect him to return from the theatre.

He was washed out from the rectum daily with saline, and from then on his condition was remarkable. In a few weeks his colour had improved, and he expressed himself as feeling well. There were three factors that may have contributed to the result—the administration of arsenic (which may have got rid of the amoebae), the pneumococcal vaccine, and the more thorough flushing of the colon by means of the appendicostomy.

On June 25th I attempted the closure of the colostomy by Coffey's method. Owing to the presence of much prolapse and a very considerable spur the operation was difficult. Every attempt was made to get a thorough invagination, several tiers of catgut being used to secure invagination of the bowel wall, and ample drainage was provided, but four days later faeces came through the drainage tube, which passed down to the peritonaeum. This, I think, was due to nongulation and the presence of the spur, which prevented the onward passage of intestinal contents into the distal segment. At the present time some faecal matter is passed naturally, but most comes through the abdominal wound, and a further operation may be required to close this. In other respects his condition is very satisfactory. A blood examination made July 20th gave: Haemoglobin 65 per cent., red blood corpuscles 4,500,000, white blood corpuscles 8,000—polymorphs 60 per cent., small lymphocytes 37 per cent., large lymphocytes 1 per cent., eosinophils 1 per cent., and basophils 1 per cent. The only organisms found in the stools were *B. coli*; the entamoebae and *B. pyocyaneus* had disappeared.

These two cases differed from tropical dysentery in that there was no ulceration, and neither the bacillus of Shiga or the *Entamoeba histolytica* could be found. There was a remarkable absence of pain in each. The mucous membrane presented a uniform granular appearance, which in the second case was observed to extend from the rectum to the splenic flexure, and which probably involved the whole lower bowel. This case was much the more severe, and we did not expect him to recover. I attribute a large share in the result to the appendicostomy, and if I had a similar case to treat which did not respond to medical methods I should perform appendicostomy, and place a large flatus tube in the rectum, avoiding opening of the bowel, which in each case was done for diagnostic reasons, owing to the difficulty in investigating the colon higher up with the sigmoidoscope.

I may conclude with a few remarks on Coffey's method of closure of colostomies. I have tried this on four other occasions. In three, after some suppuration of the abdominal wound, a satisfactory closure ensued. In one a further operation was required: It is perhaps a safer operation than resection, but where there is considerable prolapse and extensive spur formation, it is difficult and unsatisfactory. The obstacle of the spur may be got over to some extent by the use of Balfour's rubber tube for a week or two before operation, but even then I think that the necessary invagination of the antimesenteric border is likely to cause distortion and angulation of the gut. In the second place, it does not seem to be in accord with the first principle of intestinal surgery—namely, that secure union depends on the apposition of serous surfaces; as the operation is extraperitoneal this cannot be obtained. There is, however, probably less risk to life, and in suitable cases, with little prolapse, it is worth doing. China clay emulsion was also given during the later part of the treatment, but he was then recovering and its effect could not be judged.

Since the above was written, I am informed that the first patient suffered a relapse, but is now well again.

The second patient has also had a slight relapse, again passing a moderate amount of blood and mucus, and is at present being treated at his home by injections of an autogenous coli vaccine. I hope shortly to be able to close his colostomy.

NOTE ON THE INTRAPLEURAL PRESSURES IN ARTIFICIAL PNEUMOTHORAX.

BY

JAMES LAWSON, B.Sc., M.D., M.R.C.P.E.,
ASSISTANT PHYSICIAN, TOR-NA-DEE SANATORIUM.

I SHOULD like to call attention to a feature which has not, as far as I am aware, already been noted and which deserves the consideration of those called upon to supervise the treatment of artificial pneumothorax cases. I refer to the alteration which takes place in the intrapleural pressures with a change in the position of the patient.

This fact was first observed in the case of a patient in whom a right-sided artificial pneumothorax had been established. The patient always experienced a desire to cough when lying on the left side (the position in which all former refills had been carried out) and requested to be allowed to lie on his back. Puncture was made in the anterior axillary line in the fourth interspace and the manometer recorded pressures of $-2+5$, whereas the pressures reached at the previous refill fourteen days before were $-2+4$. Fluid was suspected, but the patient had been unconscious of splashing and physical examination had not suggested its presence. On rolling the patient into the left lateral position the pressures at once fell to $-4+2$.

Subsequent cases were investigated to ascertain the constancy of this variation, with the results shown in the table.

Position of Artificial Pneumothorax.	No. of Refill.	Pressures before Refill.		Quantity of Gas Introduced.	Pressures after Refill.	
		Lateral.	Dorsal.		Lateral.	Dorsal.
Case 1: Right-sided, complete, with a small quantity of fluid in the pleura	18	$-2+4$	$+2+6$	100 c.cm.	$\pm 0-5$	$-5-12$
	19	$-2+3$	$+1+6$	150	$\pm 0-6$	$-5+12$
	20	$-4+2$	$+2+5$	1,000	$+3+5$	$+8-12$
	21	-3 ± 0	$+2-7$	800	$+3-5$	$-12-13$
	22	$-1+1$	$-8+12$	700	$+6-8$	$-12+14$
Case 2: Left-sided	23	-2 ± 0	$+3+6$	700	$+4+8$	$-11-35$
	24	$-5+2$	$-2+5$	700	$+3+5$	$+4-12$
	25	$-2+7$	$+4+14$	100	$-10+17$	$+14+22$
	7	$-8+2$	$-1+2$	500	$\pm 0+4$	$+2+7$
	18	$+3+2$	$\pm 0+4$	450	$-5+10$	$+8+12$
Case 3: Right-sided, with fluid	19	-3 ± 0	$-1+2$	500	$+3-8$	$-6-11$
	20	$-4+2$	$-2+4$	500	$-6+10$	$-9-13$
	21	$-1+2$	$\pm 0+4$	400	$-6-12$	$-2-13$
	12	$-1+2$	$-2+5$	350	$-2+4$	$+4+5$
	13	-6 ± 0	$-4+5$	400	$-2+4$	$+4+5$
Case 4: Left-sided	14	-5 ± 0	$-4+4$	550	$-2+4$	$+3+5$
	15	-10 ± 0	$-5+2$	850	$-3+3$	$-2+5$
	16	$-8+2$	$-6+2$	600	$-2+3$	$\pm 0-5$
	17	$-5+2$	$-2+5$	350	$-2+4$	$+4+5$
	18	-6 ± 0	$-4+5$	400	$-2+4$	$+4+5$

In the columns headed lateral the pressures are those taken with the patient lying on the side of the functioning lung.

Figures are not available to demonstrate the pressures in the erect posture, but, in the few cases in which this has been investigated, it has been found that the pressures approximate to those found in the dorsal position.

A consideration of the pressures in the above cases will show that there is a constant rise in the pressures when the patient is moved from the lateral to the dorsal position. The importance of this observation will be recognized when an attempt is made to re-establish a previous pressure. This obviously can only be done with certainty when the patient occupies the same position on both occasions. Laplace's must therefore be laid on the fact that any statement of intrapleural pressures must be accompanied by a statement of the position of the patient.

Further, while the amount of the rise varies not only in different cases, but in the same case, it will be noted that the pressures are frequently doubled. As refills are usually conducted in the position in which the pressures are lower—

Reports of Societies.

THE ACTION OF ARSENOBENZOL PREPARATIONS.

At a meeting of the Section of Therapeutics and Pharmacology of the Royal Society of Medicine, on February 14th, with Dr. W. LANGDON BROWN in the chair, a communication was made by Dr. H. H. DALE and Major C. E. WHITE on an experimental method of determining the therapeutic efficiency of "914" preparations. In Dr. Dale's absence through illness, the investigation was explained by Dr. BURN, his colleague. In 1915 the Board of Trade asked the Medical Research Committee to undertake the biological testing of compounds of "606" and "914" which were being sold in this country. When "606" was originally made in Germany Ehrlich himself pointed out that it was essential that some biological test should be imposed on account of the continual variations in toxicity. It seemed even more important, if "606" was controlled biologically, that "914" compounds should be similarly controlled, because no similar test had been proposed for these latter preparations when they were prepared and issued in Germany. The test carried out by the Medical Research Committee was a simple toxicity test, in the shape of an injection into the tail vein of mice, and if with a given dose a certain proportion of mice survived, the batch was considered satisfactory. In the first year or so after the introduction of these substances, preparations were brought forward by manufacturers in this country which closely resembled the German products, some of which only just reached the borderline of the toxicity test, while others easily passed the test. During the war there was little opportunity of obtaining information whether changes in the process of manufacture led to any deterioration in therapeutic value, but afterwards reports came to the Salvarsan Committee that the clinical results obtained with "914" were not so good as previously. Investigations were thereupon carried out under Dr. Dale's direct supervision, in which mice infected with trypanosomes were taken as the test. The precise number of trypanosomes per cubic millimetre could be counted; at a certain point in the infection an injection of neo-salvarsan was given, and it was found that very large doses would clear out all the trypanosomes in twenty-four hours, a smaller dose would do the same in forty-eight hours, and in other cases seventy-two hours was required. If trypanosomes did not disappear in seventy-two hours they did not disappear at all, and the mouse rapidly died. The minimal curative dose was taken as the dose which removed organisms from the peripheral blood of all mice within seventy-two hours or less. It was found that preparations of "914" at first differed greatly in their power to cure trypanosomiasis in mice, and that the German "914" had a much lower minimal curative dose than the original British preparations. The British manufacturers thereupon set to work to produce something which should be more like the German product, and as a result of this investigation they considerably reduced the minimal dose, so that it now compared favourably (as was shown by tables) with the German preparations. Certain clinical results—not many, owing to the difficulty of obtaining them—had been tabulated, and the correlation between these and the experimental results with the same given set of preparations proved to be fairly close. A test was now regularly imposed on preparations of "914," not merely for toxicity, but for therapeutic value.

Dr. MACKENZIE WALLIS at the same meeting read a paper in which he referred to the toxic action of arsenobenzol compounds on the liver, and described investigations with the object of discovering whether such compounds, when administered to patients, produced changes in the liver sufficient to give rise to disturbances of liver function without producing any obvious signs and symptoms of such toxic action. As a result of the trial of many testing methods, he had come to the conclusion that the tests which were of value were three in number: the levulose tolerance test, the blood lipase content, and the cholesterol content of blood. He described each of these, and said that the levulose tolerance test served to show that the maximum effects on the liver after injections of novarsenobenzol were exemplified from three to three and a half months after the last dose, and that six months after the last dose the liver had regained its function in regard to levulose. The greatest effect of hepatic damage occurred three months after the last treatment. The

lipase test proved to be much simpler in its application and quite as valuable in the results obtained, and here again it was found that the maximum effect was exemplified three months after the last treatment. Of the various tests, he advocated the adoption of the lipase test as the one which could be universally applied.

Dr. T. H. G. SNORE gave an account of the effect of arsenobenzol treatment on the kidney and liver as he had seen it in *post-mortem* examinations which he had conducted at Etaples during the war. His observations related to 23 cases in which preparations of the "914" group had been used, and in 11 cases the death apparently was the result of jaundice. From such clinical history as he had been able to gather he found that these people did not develop their jaundice until three weeks or a month after their treatment had been completed, and when they did develop it they died very rapidly. Unlike Dr. Turnbull in some similar investigations, he found that the liver in these cases was devoid of fat, but he found fat in the kidney, and he believed that the fat which ordinarily accumulated in the liver by the time the cases reached him for *post-mortem* examination had got into the kidney for excretion.

In the subsequent discussion Mr. J. E. R. McDONAGH referred to 67 cases of jaundice seen at the Lock Hospital, in nearly all of which the jaundice had appeared in the twelfth week after the last injection. Sir P. BASSETT-SMITH referred to the importance of testing all these powerful drugs by biological processes. Dr. SPENCE alluded to the most definite reduction of liver efficiency in catarrhal jaundice. Professor A. J. CLARK referred to some cases in which it had been possible to detect the effects of large doses of salvarsan given intravenously upon horses which had to be destroyed, and the *post-mortem* signs were almost identical with those of arsenical poisoning, as if the arsenic had been taken by the stomach. Dr. W. E. DIXON deprecated any talk of salvarsan as though it were a special kind of drug; it was only arsenic, and the difference between these organoarsenical compounds was a question of their dissolution more easily in one tissue than in another.

THE IDEAL PSYCHIATRIC CLINIC.

At a meeting of the Section of Psychiatry of the Royal Society of Medicine, on February 14th, with Dr. BEDFORD PIERCE in the chair, "The ideal clinic" was the subject of a discussion which is to be continued at the next meeting.

Dr. HELEN BOYLE, in opening, urged that an out-patient department alone would not suffice for a psychiatric clinic. Beds were necessary, often because the patient's domestic surroundings interfered with treatment, and also because to carry out the various forms of treatment required in many cases continual observation and supervision. The clinic should be established in the town rather than in the country. In the town it would have the advantage of association with a big general hospital; also it would be more accessible to out-patients. The advantages of quietness in the country were more imaginary than real, and perhaps were more easily dispensed with by mental patients than by others. Such patients often found the country boring and irritating; while, on the other hand, the streets and shops in town were so various and interesting that the most introverted patient must to some extent respond to these stimuli. The clinic building should consist of an administrative block with observation wards on each side, and certain association rooms for gymnastic and social purposes. There should also be smaller wards for four, five, or six patients, which was a better grouping than two or three patients. The solitude of single rooms would seldom be found necessary. The patients eligible should include children, for these disorders should be tackled at an earlier stage than hitherto. In the United States and Canada children who got into the hands of the law were often referred to such institutions. She thought that it would militate against the best interests of the clinic to seek powers for compulsory detention. The locked door suggested force and mystery, induced fear in the mind of the patient, hindered treatment, and damaged the tone both of patients and staff. The most happy thing that could be said to any incoming patient was that he or she was perfectly at liberty to go home. On the other hand, a few patients were comforted by locked doors.

The treatment (Dr. Boyle continued) should include, in addition to all hydrotherapeutic and physical methods, occupational therapy, which offered a safety valve for emotional

strain. One American clinic even went so far as to allow a patient to learn embalming because that was his fancy. Games and concerts were of use, and so various and subtle was the curative treatment of a mind diseased that she had found a visit to the penny bazaar of service in the re-education of patients. Religion was very important, and there should be a chapel in the clinic, simple, beautiful, and non-sectarian. When the clinic was in association with a general hospital the medical staff would be chosen in the same way as the hospital staff. There should be part time men and women practitioners, aided by house physicians. The members of the staff should have real working experience of a mental hospital. Probably both out patients and in-patients would have to be fewer in number in relation to the number of doctors employed than was the case in general hospitals. The nursing staff should be selected with great care as to temperament and personality. She looked forward to the time when they would prescribe people as they prescribed drugs, assigning to this patient a vivacious nurse, and to that a quiet one. Every clinic, also, should have social service workers who would go and collect the data with regard to the patients. Contrary to what might be expected, she found that in America such workers were very popular.

Dr. W. A. Potts did not agree with placing the ideal clinic in a general hospital; that was not Utopian, but pre-Victorian. With a few exceptions, the staffs of general hospitals did not understand psychotherapy or the new psychology.

Dr. H. M. B. Bopp questioned Dr. Boyle's postulation of a clinic with out-patient and in-patient work under the same roof. The out-patient department would do great good, but, unless the general attitude towards mental disorders underwent a change, it would be impossible to get the out-patients without disguising the nature of the institution. The successful clinic would be part and parcel of the general hospital, and would bear its name, although it would be a distinct unit. When the moment came for these clinics to mature he hoped that the bogey of certifiability or non-certifiability would not be raised.

Dr. R. B. ARMSTRONG-JONES gave some account of an out-patient mental department which he carried on for two years at St. Bartholomew's. It had been useful, but he could not help a feeling of disappointment. The people who attended were largely chronic epileptics. The incipient insane would not see himself as others saw him. The mental hospitals were the proper places in which to treat incipient cases, and he did not like the suggestion that the experience and organization accumulated there should be put on one side.

Dr. B. H. COLE supported the idea of a clinic away from the mental hospital. It seemed to him that his duty in an out-patient department was to decide where a given patient should be located; he was quite certain that in that way he had been able to prevent a good many cases from drifting into mental hospitals.

Dr. CHURTON MILLER said that Dr. Boyle had omitted to speak of the biggest element in the problem—the amount of time the treatment took. At the Tavistock Clinic, in the first year of their work, the average length of each interview was forty-nine minutes. At a large hospital there must be a certain amount of red tape, and red tape killed psychotherapy. The most valuable work could be carried on at a clinic while the patients remained at their work during treatment.

The discussion was adjourned until the March meeting of the Section.

X-RAY TREATMENT OF CANCER.

At a meeting of the Oxford Medical Society a paper on recent advances in the x-ray treatment of cancer was read by Dr. H. K. WARD, who last July had had the opportunity of seeing the work being done at the Universitäts Frauenklinik, Erlangen, Bavaria. He gave a brief description of the technique elaborated by Professors Seitz and Wintz, at Erlangen, the principles on which it was built up, and the results obtained by it in the treatment of fibromyomata and malignant disease.

Dr. Ward said that Professor Wintz, although not the first worker in this field, had made a number of improvements both in the apparatus used and in the measurement of x-rays. The apparatus was a powerful one, consisting of two coils, and giving a 16-in. parallel spark gap. The x-ray tube had an ingenious mechanism which automatically kept the vacuum constant, and it was claimed that, working with very high tension currents, this tube lasted longer on the average

than the Coolidge tube. Professor Wintz early discarded the Kienböck strip and the Sabonrand pastille for measuring x-rays, the former as unreliable for rays of different hardness, the latter as not giving sufficiently accurate graduations. He then developed the ionoquantimeter, invented originally for this purpose by two Frenchmen, Villard and Szilard, and had used this method ever since.

Professors Seitz and Wintz had laid down what they call the optimum therapeutic dose for various diseases. If the erythema dose was called 100 per cent. the dose that the ovaries must receive to sterilize the patient was 34 per cent., the dose to kill carcinoma cells—the so-called carcinoma dose—was 90 to 110 per cent.; the sarcoma dose was 80 per cent., and so on. It was stated that if carcinoma cells received 40 per cent. they were stimulated and grew faster than ever. If the rectum received 135 per cent. a severe diarrhoea resulted, and if the intestine received 150 per cent. it would ulcerate and perhaps perforate. The figures might not be quite accurate; indeed, other workers did not entirely agree with them, but it was at any rate the right method of tackling the subject, if controlled by accurate measurement of the rays. It aimed at giving a definite dose in a definite region, and had introduced a much more scientific method of x-ray therapy than had obtained in the past. The above figures at once stimulated the x-ray worker to elaborate new techniques to bring these doses to bear on diseased tissues, and limited him in other directions because of the destruction of normal tissues.

In the treatment of fibromyomata the Erlangen technique was to sterilize the patient by giving each ovary 34 per cent. of an erythema dose. The haemorrhage soon ceased, but the tumour only began to shrink some months after the treatment. There appeared to be very few contraindications, and, according to the authors, even accompanying tubal inflammations subsided in time. It was interesting to note that, if a dose of approximately 28 per cent. be given the ovaries, a temporary sterilization often resulted—that is, menstruation ceased for some months, to return again later, the explanation being that the more mature Graafian follicles succumbed, but the immature follicles were more resistant and survived.

The Erlangen school had had more experience with the treatment of cancer of the cervix uteri than with any other cancer. They began by combining radium with the x-rays in the treatment of this cancer, but later discarded radium as unnecessary. They concentrated six erythema doses upon the cervix, using three ports of entry in front and three behind. Unless great care was taken, the rectum lying just behind the uterus would receive a dosage which was often sufficient to excite a very severe diarrhoea. For another reason no more than six erythema doses should be given at one sitting; the blood even with this dose suffered considerably, showing notably a destruction of red cells and lymphocytes. However, the blood recovered in six weeks' time unless the disease was far advanced, with pronounced cachexia and anaemia. In these cases the blood never recovered, and the patients invariably died.

They devised a technique which they called the Roentgen-Werthem, in memory of the two men on whose work it was ultimately founded. This technique was carried out as follows: (1) Treatment of the cervix uteri with six erythema doses concentrated on the cervix uteri. (2) Treatment of the parametria. This could not be carried out at once, because six erythema doses is a very severe dose of x-rays from which the blood alone takes some weeks to recover. The authors had fixed on six weeks as the interval which must elapse before a second set of six erythema doses was given to one parametrium. As before, three ports of entry were used in front and three behind, all concentrated on the parametrium. After another six weeks' interval the other parametrium was treated in a similar fashion. The results with this technique had been extremely promising so far, and the authors claim a very much larger percentage of successes than with any other known form of treatment. Indeed, they said that cure was almost certain if the disease was not too far advanced. Naturally they did not claim to be able to cure cases with metastases and profound cachexia and anaemia. Their experience of cancer of the breast was limited. Here the problem was a different one. Instead of a centrally situated tumour which could be approached from all sides there was a tumour lying close underneath the skin whose base was at most 3 to 5 cm. below the skin. If the breast was poorly developed it was impossible to use even two ports of entry because the two bundles of rays would cross just beneath the skin, and the tissues would be burned. The axillary glands

were of course treated as well, and given the carcinoma dose. No actual results had been published, but they were understood to be quite promising. The same could be said for carcinoma of the vulva. In this case the technique was the same as in a cancer in a poorly developed breast. In cancer of the stomach the results were not very promising; it was indeed as unfavourable a form of cancer to treat with x rays as it was by operation. It was often diagnosed only late in the disease, when there were already metastases in the liver. Another complication was that the tumour itself was generally quite close beneath the skin, while the glands lay deeper. The results were not good, but were understood to be improving as more experience was gained.

With regard to the treatment of sarcoma, the problem was at the same time simpler and not so simple. A sarcoma formed metastases by way of the blood stream, and might, while still quite small, have already given rise to metastases in the lungs. Carcinoma, on the other hand, spread more slowly by the lymph channels, and its extension was held up temporarily by the lymph glands, so that it remained local for some considerable time, thus lending itself to local treatment by x rays. The disappearance of the main sarcomatous tumour might be dramatic after x -ray treatment, but there might be already formed metastases in distant organs, which were beyond treatment. Nevertheless, Seitz and Wintz were of opinion that the prognosis in fairly small sarcomata was on the whole favourable.

In Dr. Ward's opinion, credit was not so much due to Krönig, Friedrich, Seitz, Wintz, and other workers for the powerful apparatus which they had devised—though this was a considerable factor in their success—as it was for their introduction of proper scientific methods into the problems connected with the dosage of x rays. First, the actual measurement of the rays with an accurate instrument, then the measurement of the percentage deep dose at various depths, and the study of the various ways in which this percentage deep dose could be increased; then the estimation of the optimum therapeutic dose in different diseases which should be aimed at; and lastly, the various techniques devised in order to get that dose where it was wanted without seriously injuring the normal tissues; and among these techniques the Roentgen-Wertheim technique invented by Seitz and Wintz stood out as the most promising and successful. A note of warning should be added. This method of carcinoma therapy was such an extensive one, the therapeutic dose was so near the dangerous dose, that unless the x -ray worker had an intimate knowledge of the apparatus, the technique, and the principles on which it was based, more harm than good might result. This was unfair to the patient, as it was to the method of treatment.

Dr. W. J. TURRELL took a more pessimistic view of the future of x rays in the treatment of cancer. He said that uterine cancer was less resistant to x rays than certain skin cancers, and this was the explanation of the more favourable results obtained. He spoke in favour of divided doses, and thought the Roentgen-Wertheim technique for uterine cancer much too risky, on account of the danger to the intestines and the general reaction produced. He put in a plea for the development of methods to sensitize the cancer cells, so that they would be killed by smaller doses of x rays.

FLAT-FOOT AND ITS COMPLICATIONS.

An ordinary meeting of the West London Medico-Chirurgical Society was held at the West London Hospital on February 3rd, with the President, Sir GEORGE LENTHAL CHEATLE, K.C.B., in the chair. Mr. H. A. T. FAIRBANK read a paper on flat-foot and some of its complications.

Mr. Fairbank began by disussing the progress made in recent years in the treatment of ordinary cases of flat-foot. In children flat-foot arose as a result of congenital deformity, muscular weakness, or absence of the normal reflex postural activity of the muscles supporting the foot. In adults overwork or weakness were two of the causative factors of ordinary flat-foot. He drew attention to the work of Sherrington and others on the "postural activity" of the anti-gravity muscles, failure of which might account for the development of static flat-foot. Re-education of this reflex was necessary for its cure. Pain was conspicuous by its absence in children and most adolescents, and in these subjects a cure was usually possible. In adults, however, relief of symptoms only was the rule. He spoke warmly of the satisfactory results obtained by electrical stimulation of the

muscles, especially by Dr. Murray Levick's method by which the tone of the small muscles of the foot was re-established. This treatment should be combined with suitable exercises, every effort being made to interest the patient in his treatment, the "mental effort" on his part being an all-important factor. In children, wedging-up of the inner side of the sole and heel of the boots, and stiffening the inner side of the "upper," should be employed in addition. In adults electrical treatment often gave marked relief of pain, but in addition in these cases "sole-plates" were usually necessary. These plates should be made for each individual, plaster casts being taken and carved up suitably after Trothowan's method. He described and demonstrated this method in detail. In children contracture of the calf muscles was a complication sometimes met with. This could be overcome in milder cases by stretching, while tenotomy of the tendo Achillis might be necessary in the severer forms. He mentioned osteo-chondritis of the heel epiphysis and that of the tubercle of the navicular as causes of painful flat-foot in children. The pathology of the condition was similar to that of "Schlatter's knee." Köhler's disease, or "isolated disease of the navicular," was another cause of pain in children. Lastly, he drew attention to the frequent development of flat-foot after convalescence from illnesses necessitating prolonged confinement to bed, the absence of reflex postural tone accounting for this. The paper was illustrated by numerous radiograms and plaster casts.

Mr. McADAM ECCLES considered that all infants were born with poorly developed longitudinal arches, the arch developing as the child grew. Flat-foot in children was therefore more often due to non-development of the arch than to flattening subsequently. He agreed with Mr. Fairbank as to the efficacy of electrical treatment and the frequency of flat-foot developing during convalescence from long illnesses. He had seen a number of cases of epiphysitis of the proximal end of the first metatarsal in lads about 12 years of age the subjects of flat-foot.

CONGENITAL STENOSIS OF BILE DUCT.

A MEETING of the Pathological Society of Manchester was held on January 18th, with the President, Mr. J. Howson RAY, in the chair, when Dr. J. F. WARD described a case of congenital stenosis of the bile duct and patent interventricular septum.

The history of the case was that of a first child, born at term, both parents healthy. It was apparently healthy at birth, but jaundice was noticed at the age of 3 days; this soon became marked and remained so with very little variation until death. The child was first seen at the age of 5 months, when there was marked jaundice; the weight was 7 lb. 12 oz., the liver was enlarged, the spleen not palpable. There was a systolic murmur over the whole of the precordium; the pulse rate was 120 to 140; the Wassermann reaction was negative. The child was kept under observation as an out-patient until one week previous to death; the weight was then 7 lb. 14 oz. Death took place at the age of 8 months.

On post-mortem examination the organs were found to be deeply bile-stained. The liver and spleen were enlarged, the surface of the liver smooth; the gall bladder was small. The actual site of obstruction of ducts was not definable without injection. There was no ascites. The heart had a small opening in the upper part of the interventricular septum, but there were no other malformations. On microscopical examination of the liver there was a very slight degree of biliary cirrhosis.

The case resembled those previously described in its clinical course. There was nothing to suggest any etiological factor, but the coincidence of a congenital defect of the heart and very slight degree of cirrhosis suggested malformation of ducts rather than inflammatory stenosis.

Mr. J. Howson RAY showed a large renal calculus of unusual size and shape removed from the left portion of a horse-shoe kidney from a male aged 49 years. This calculus had a curious resemblance in shape to a hand with four finger-like processes, the lowest of which was tipped with a scale of phosphates simulating a finger-nail, whilst the rest of the calculus was coated with a deep reddish-brown film of urates. The lowest process projected from the dilated pelvis into the upper end of the ureter. The left kidney was little more than a shell of atrophied renal tissue, which closely embraced the calculus, and was joined by a bridge of kidney substance to the lower pole of the right kidney across the vertebral column. The right kidney was hypertrophied. The calculus weighed 3 ounces 15 drachms. The patient at the age of 16 years was treated for stone impacted in the penile urethra. He had no further obvious trouble until the past year, and for a

little over six months had suffered from pain in stomach, constant indigestion, and flatulence, but had no pain in micturition and no increase in frequency of micturition. The calculus and left kidney were removed by the abdominal route and uninterrupted recovery followed.

Mr. J. PHILIP BUCKLEY showed a case of endothelioma of the stomach, removed from a young woman who had presented signs similar to those due to perforation of an ulcer. A partial gastrectomy was performed, with successful issue.

Mr. J. B. MACALPINE showed five urinary specimens of considerable interest, including a ureterocele, which had been removed from the lower end of the left ureter. The speaker believed that a condition in this case the kidney of a child and in the urine, and an examination of the urine of the seven other members of the patient's immediate family revealed similar crystals in three other individuals who had no symptoms. A large papilloma in the pelvis of a kidney, an extensive papillomatosis of the bladder, for which that viscus was removed after transplanting the ureters to the surface of the body, and a dissection of a case of ectopia vesicae were exhibited and discussed.

Mr. GARNETT WRIGHT, Mr. H. H. RAYNER, and Mr. JOHN MORLEY showed other cases and specimens of interest.

PULSE TRACINGS AND THEIR MEANING.

A MEETING of the West Kent Medico-Chirurgical Society was held on February 10th, at the Miller General Hospital, Greenwich, when Dr. C. O. HAWTHORNE gave an address entitled "Some pulse tracings and their meanings." Dr. Hawthorne analysed the sphygmographic wave, and by comparing its form with the sphygmometer maximum in different groups of cases argued that the pulse tracing gave no information as to the height or level of blood pressure; its message, in so far as blood pressure was concerned, was related to the endurance of pressure and to the fashion of its decline. Only in this way could be explained the fact that with one and the same sphygmometer maximum the sphygmographic pictures in different cases might vary widely in their forms and meanings, and that with similar or identical tracings the sphygmometer level might differ. The interpretation of this variety must be found in the suggestion that the sphygmometer registered the height to which the pressure rose, but gave no information of the endurance of pressure, while the sphygmograph, on the other hand, displayed the form of pressure—well-sustained or ill-sustained—but made no announcement of its numerical level.

The address was illustrated by numerous tracings and sphygmometer records in exemplification of the above argument, and by others showing the effects of various drugs on the peripheral circulation.

A MEETING of the Pathological Section of the Sheffield Medico-Chirurgical Society was held in the Pathological Department of Sheffield University on February 9th, when Dr. GODFREY CARTER, the President, in the chair, when Dr. A. G. GIBSON read a paper on the pathology of epilepsy. He urged that an attempt should be made in every case of epilepsy to discover a definite cause, and that if such an attempt were sufficiently painstaking a large number of so-called "idiopathic" cases would be found to be definitely assignable to some organic disease. Of such organic causes of epilepsy Dr. Gibson drew attention to circulatory changes, and instanced the seizures that occurred in the course of Stokes-Adams disease. He also pointed to the interesting connexion between epileptiform convulsions and the infectious fevers, and laid stress on the extreme importance of syphilis as an etiological factor in the production of the disease, stating that no case had been fully investigated until a serological examination had been carried out. Amongst the causes of epilepsy were to be found such definite entities as parasitic disease of the brain. The term "idiopathic" should be avoided when dealing with epilepsy until every possible source of recognizable etiology had been excluded. Until this had been done, simple administration of bromides was to be deplored.

At a meeting of Glasgow Southern Medical Society on January 19th Mr. R. H. PARRY delivered his presidential address, taking as his subject "After-treatment." During the period since he was a house-surgeon the technique

of surgical operations had advanced to a very high state of perfection, and methods of diagnosis had also greatly improved, but as regards after-treatment much remained to be done. He laid stress on the effects of early diagnosis in simplifying after-treatment, and showed that after-treatment, which was often apt to be regarded as drudgery, might be made a very interesting study resulting in great benefit to patients. He laid stress also on the need for closer co-operation between the hospital surgeon and the general practitioner, by whom the after-treatment ought usually to be carried out, and ended by saying that the gulf that existed between hospital treatment and that outside must be bridged. Quackery had its biggest scope in the failures in after-treatment.

Rebichus.

MEDICAL PRACTICE IN THE TROPICS.

THE scope and object of *The Practice of Medicine in the Tropics*, by many authorities, edited by Colonel W. BRAM and Major R. G. ARCHIBALD, the first volume of which is before us, is explained in the preface: "The primary object of the Fellowship of Medicine being to promote a closer relationship between the members of the medical profession throughout the English-speaking world, we have attempted to help this endeavour by producing a book which will serve the student as an introduction to the leading teachers of tropical medicine throughout the British Empire, in the United States of America, and in other countries where the English language is spoken." The authors believe that tropical medicine offers a particularly favorable field for the promotion of an international *entente* such as they are endeavouring to bring about. The book has been planned to include articles on diseases which are not peculiar to warm countries, but which present aspects of importance to practitioners in the tropics. Chapters on nursing, diseases of women, and the production of small-pox vaccine are also included. The authors' endeavour, they tell us, has been to produce, not an encyclopaedia, but a work of reference which will meet the practical needs of the average man in the tropics. The frontispiece is an excellent photograph of Sir Patrick Manson. The list of contributors, numbering seventy-eight in all, contains many names well known in tropical medicine, and the authors of the work are to be congratulated on their choice, which has provided representatives of every aspect of the subject. The main sections in the first volume are hygiene and minor tropical sanitation (pp. 1-258), nursing, entomology (pp. 271-494), laboratory methods (pp. 495-682), snakes and snake poisoning (pp. 683-762), and toxicology (pp. 738-855); there is also a good general index. Dr. Balfour, who is responsible for the first section, has produced a very interesting and readable article; it is abundantly illustrated, and should be very helpful to intending visitors to the tropics, warning them of the dangers to health they are about to encounter and how best they can avoid them. Entomology is fully dealt with by a series of writers, including C. Warburton, Lt. Lloyd, M. E. MacGregor, L. O. Howard, H. H. King. Here again the coloured plates and other illustrations are of a high order of merit, and contribute to an understanding of the text, which is well chosen and well written. The article on laboratory methods—a subject of paramount importance in the tropics—has been written by R. G. Archibald, the joint editor of the work. Here again a well-balanced, up-to-date article has been produced, containing all modern methods of importance, and good accounts of the examination of blood, faeces, urine, etc.; at the end is a useful note on post-mortem examinations. A statement on p. 605 that the cervical glands are enlarged in infection by *Filaria perstans* is open to criticism. Why should they be? The adenoids live in the mesenteric tissues, not in the glands, and their embryos are in the blood stream; adenitis, when it occurs, must be due to some other infection, and not to the filaria. No mention is made of calcified filariae (*F. immanis*) in the tunica vaginalis and epididymis; they should always be carefully searched for as they afford evidence of an old filarial infection. When writing of multiple abscesses the small multiple amoebic abscesses are not specially commented upon, while the statement as to the diaphanous condition of

The Practice of Medicine in the Tropics. By many authorities. Edited by W. BRAM, O.B.E., Lieutenant-Colonel, R.A.M.C. (ret.), and R. G. ARCHIBALD, D.S.O., M.D., Major, R.A.M.C. (ret.). Vol. I. Oxford: Medical Publications, London: Henry Frowde, and H. K. Lewis & Co. 1921. (Roy. 8vo, pp. xxii + 855; 331 figures, 35 plates. 2s. 4d.)

the gut in kala-azar is open to dispute. *Asearis* in the larynx might have been mentioned on p. 613, and *paragonimus* and helminthic lesions in the brain on p. 614.

The chapter on serums and vaccines, by Colonel D. Harvey, is specially interesting, giving as it does a very clear conception of the matter; it should prove of the greatest use to the worker in the tropics. The section on snakes is written by Major Acton, I.M.S., in collaboration with Major Knowles. It is well illustrated, and contains much useful information. Dr. H. H. Scott, the discoverer of the part the akee plays in vomiting sickness, appropriately deals with vegetable and fish poisoning in the tropics. Lastly, Mr. Colles discusses the chemical investigation of medico-legal cases, an intricate and very difficult subject. It will be gathered from what has been said that the volume contains a wealth of material which will be most useful to many workers in different branches. Mention has already been made of the excellent coloured plates (35 in all), and of the other illustrations by which its pages are so profusely adorned. These lighten the tedium of reading through the text, and make the understanding of it much more easy. The standard set by this volume is high, and if this level is maintained in the other two volumes, which are to deal with the diseases proper, then the book may well become the authoritative standard reference work in English on tropical medicine.

THE ART OF GROWING OLD.

DR. LAPHORN SMITH has written a very readable, interesting and instructive little book entitled, *How to be Useful and Happy from Sixty to Ninety*.² It manifests throughout the work of a keenly observant man with multiform knowledge by no means confined to matters strictly medical. The author has certainly collected ample evidence in favour of the contention implied in the title of his book. Although a large part of this work consists of concrete examples of happy and useful lives led by men and women long after arriving at sixty, and by many up to ninety or over, there is no lack of illuminating comment on the way in which they achieved success. Apart from his repeated emphasis on the generally received medical maxims concerning sobriety, early rising and going to bed, dieting, and so forth, the author's insistence on the extreme importance of physical and mental exercise appropriate to each individual case, and continued persistently without counting the years as they pass, may perhaps be said to be the chief feature of his teaching. This is not to say that the book is marked by any dull repetition, for each chapter is enlivened by fitting anecdotes, by records of the author's own experiences, and by his evident conviction of the truth of the teaching he endorses.

Dr. Laphorn Smith dwells much on the harm of too much meat food for the old and elderly, of alcohol in any but small amounts, and of tobacco smoking generally. But in his last chapter, entitled "Axioms for the man over sixty," which is well worth studying and generally following, one of the axioms runs thus: "If you have been a smoker all your life keep on smoking in moderation, and if you have been a moderate drinker, keep on drinking in moderation (if you can get it)." In view of the author's somewhat excessive tirade against tobacco in Chapter XIII—where he surely exaggerates the number of persons who suffer from tobacco blindness, and probably of those who have disordered heart action from over-smoking alone, and thus draws the conclusion that 1 oz. a week is the limit of safety for a smoker—he is certainly to be credited with a generous exercise of his common sense and humanity when he enjoins a man over 60 "to keep on smoking." He seems not to be aware that a man who has smoked all his life and would be satisfied at 60 with 1 oz. if he could afford more, is not often to be found. Moreover, he makes no mention of the quality of tobacco smoked, a matter which general medical opinion holds, we believe, to be one of much importance.

But it may safely be said that in spite of a few other minor criticisms which might possibly be made here and there, of this book, no one could be harmed, and most would greatly benefit, by following the author's rules without doubt or quibble. We wholly agree with Sir Charter Symonds in wishing this attractive and useful volume "bon voyage" and a long one.

² *How to be Useful and Happy from Sixty to Ninety*. By A. Laphorn Smith, B.A., M.D., M.R.C.S., etc. With a Foreword by Sir Charter Symonds, M.D., M.S., F.R.C.S., K.B.E., C.B. London: John Lane, The Bodley Head, Ltd. 1922. (Cr. 8vo, pp. xiv + 235; 1 portrait. 5s. net.)

INTELLECTUAL EVOLUTION.

THE book on the genesis of psychical energy³ which Dr. DANYSZ has written is an essay in biological philosophy. It is an attempt to mark out the place man occupies in Nature, and by tracing his evolution from the simplest forms of living matter to make a guess at the future progress of the individual and the State. It is divided into four sections: the first describes the evolution of man, the second details the reactions of living matter, the third gives an account of evolution generally, and in the fourth some general conclusions are stated. In this fourth section the author attempts a forecast of the lines upon which the human race is likely to develop in the future. His work may be recommended to the general reader; it is suggestive, and illustrates the difficulty of applying biological methods to the elucidation of psychological problems.

It is impossible to give the argument of the book and to explain the author's reason for his conclusions in a few words. He is an optimist, believing that man has not yet reached the highest intellectual development of which he is capable, nor human society the organization which will best ensure the greatest happiness for the greatest number. As a good evolutionist he is no believer in the doctrine of revolution so loudly preached by some to-day; in fact, he considers that quite a number of people who believe themselves leaders of "advanced" thought are, in fact, marching into the desert at an obtuse angle with the true line of advance. But though an optimist, he thinks that progress towards a better state of society must be slow, for the process of evolution needs much time, many generations, to achieve its beneficent results. Man is distinguished from the rest of the animal world by his intellect, and it will be by the evolution of his intellect that he will advance, but he "is not, and never will be, free to evolve in a direction arbitrarily chosen." The age of reason is coming; the present epoch will be remembered in the history of humanity as that in which "the sentiments and the passions were insufficiently controlled by the reason." For Dr. Danyesz the doctrines of Marx are not constructive because they do not appeal to the desire for new and fruitful research, but arouse passions whose manifestations are the more opposed to progress the less enlightened the minds affected.

The merits and demerits of socialism of various shades and of anarchism cannot suitably be discussed in a medical journal; we have merely endeavoured to give a general indication of the argument of this book because M. Danyesz is a distinguished biologist, because the book is suggestive, and because the biological aspect is usually neglected by political writers to whom this essay is primarily addressed.

NOTES ON BOOKS.

PROFESSOR BERNARD'S book on pulmonary tuberculosis⁴ gives, from the French point of view, a picture of the disease in its clinical and sociological aspects, and may be read with profit by medical officers of health, medical men, and nurses who have to deal with phthisical patients. Originally designed to stir the inertia of the French, who are not yet, according to the author, fully awake to the necessity for an active antituberculosis campaign in their own country, this volume may be recommended also to the tuberculosis experts of Great Britain, for it throws interesting sidelights on problems that occur in our own country just as they occur in France, and on the solutions thereof that have been found and are in working order in England but are still to seek in France. Professor Bernard is all in favour of the governmental control of tuberculosis, and we trust that his well-written volume may meet with the attention it deserves.

The book on respiratory training⁵ by Dr. J. PESCHER, who, we believe, practises in Paris, is the work of a whole-hearted enthusiast; he holds that most of the organic and functional ailments of children and adults can be cured or vastly ameliorated by graduated breathing exercises, use being made of his own variety of spirometer. The book is wordy; in

³ *La Genèse de l'Energie Psychique*. Par J. Danyesz; avec une lettre-préface de J. Payot. Paris: J. B. Baillière et Fils. 1921. (Demy 8vo, pp. 312; 25 figures. Fr. 12.)

⁴ *La Tuberculose Pulmonaire. Études de Phthisiologie Clinique et Sociale*. Par Professeur L. Bernard. Paris: Masson et Cie. 1921. (Demy 8vo, pp. 258. Fr. 10 net.)

⁵ *L'Entraînement Respiratoire par la Méthode Spiroscopique. Applications Pratiques en Hygiène, en Prophylaxie, en Thérapeutique*. Par J. Pescher. Ancien interne des hôpitaux de Paris. Paris: A. Maloine et Fils. 1921. (Cr. 8vo, pp. 287; 33 figures. Fr. 10.)

style it seems designed for the layman, but in matter it is more suitable for the medical practitioner. Rules for the application of the breathing exercises are given, and the amount of the respiratory work to be done by the patient is specified for each disorder. It would seem that Dr. Pescher expects too much of his method.

The authors of a little French book, the clinical interpretation of laboratory reports, have set out in tabular form the conclusions to be drawn by the medical man from the reports he receives on the specimens sent to the pathological laboratory for examination. Comparatively little is said as to the methods employed; given his report, the medical practitioner will find in this book all the different interpretations that it may bear, or all the diseases or disorders it may suggest. At the end of the volume is a synoptic table in which the various diseases come first, and have opposite to them a list of the pathological changes in the blood, urine, faeces, and so forth, to which they may give rise. The book is well arranged and full of information, but has the fault of increasing the separation between clinical diagnosis and laboratory diagnosis that is so frequently deplored by physicians and pathologists alike.

The first number has appeared of a bi-monthly medical review entitled *Les Néoplasmes*, which is to be devoted to original articles, abstracts, and reviews dealing with the etiology, pathology, and treatment of tumours, malignant and benign. In addition to an analytical review of current literature the first number contains original articles on the blood corpuscles in cancer, and on the treatment of cancer of the tongue. The new journal is published by Messrs. Vigot Frères, 23, Rue de l'École de Médecine, Paris, VI^e, and the annual subscription (foreign) is 18 francs.

The name of the *Journal of Orthopedic Surgery* (Boston, U.S.A.) has been changed to the *Journal of Bone and Joint Surgery*; it will be published quarterly.

Comment Interpréter en Clinique les Réponses de Laboratoire. Par Ruel, Delater, and Zoeller. Paris: A. Maloine et Fils. 1922. (Cr. 8vo. p. 133. Fr. 5.)

MEDICINAL AND DIETETIC PREPARATIONS.

Phyllosan.

PHYLLOSAN is a preparation made up in tablets; each tablet is stated to contain 0.03 gram chlorophyll and 0.005 gram iron. The agents in this country state that the preparation is known by the name phyllosan in English-speaking countries, in Germany and Switzerland as chlorosan, with or without the name Buergi, and in Spain and Italy as foliosan.

The therapeutic value of chlorophyll was discovered by Professor E. Buergi, of Berne. He and his pupils made extensive laboratory experiments upon the action of chlorophyll on anaemia in rabbits, and also made clinical observations on the action of chlorophyll combined with iron in anaemia and various other diseases. Buergi^{1,2} found that chlorophyll, when given to rabbits made anaemic by bleeding, had an action equal to that of iron in stimulating blood regeneration, and that a combination of chlorophyll and iron was much superior to either substance given alone; it was also found that chlorophyll and iron caused an increase in the haemoglobin content and erythrocyte content of the blood of normal rabbits.³

From clinical observations Buergi concluded that a combination of chlorophyll and iron was much superior to any preparation containing iron alone in the treatment of chlorosis and of secondary anaemias of various types. Buergi also found that a combination of chlorophyll and iron was of great value in the treatment of numerous diseases, particularly tuberculosis, cases of cardiac disease due to weakness of cardiac muscle, arterio-sclerosis, and cases of general debility. He concluded that chlorophyll acted as a general stimulant on the body tissues, and increased the vital force of the patient.

Buergi prepared a combination of chlorophyll and iron which he termed chlorosan, and this has been put on the market in England under the name of phyllosan. Phyllosan is stated to be prepared according to Buergi's directions, and is advertised in a pamphlet in which Buergi's claims as to its extraordinary therapeutic value are fully set forth.

The obvious question at once arises as to why the administration of iron, together with the addition of green vegetables to the diet, should not produce the same effects, only at much less cost, as those produced by the administration of phyllosan. Buergi meets this objection by saying that chlorophyll is not absorbed when given in its natural form, and that it is only of therapeutic value after it has been submitted to special purification. The results obtained by Buergi's pupils agree completely with those obtained by Buergi himself, but we can only find record of one research upon the action of phyllosan which was done outside Professor Buergi's laboratory; it was performed by Dr. W. Loeffler,⁴ who made extensive chemical, pharmacological, and clinical tests as to the action of phyllosan (or chlorosan), and obtained negative results. Loeffler found that the phyllosan tablets contained less than 0.003 gram of chlorophyll, and calculated that 10 grams of spinach contained as much chlorophyll as fourteen phyllosan tablets. He found that phyllosan was inferior to Bland's pills in the treatment of anaemia, both in the laboratory and clinical tests. He considered that there was no certain evidence that chlorophyll had any therapeutic action, and argued that even if chlorophyll had a therapeutic action it was unlikely that the minute amounts present in phyllosan would be effective. These conclusions naturally evoked a lively controversy in the Swiss medical press.⁵

It is very difficult to decide on the merits of a preparation whose action is a subject of acute controversy. The chief laboratory evidence that phyllosan has any therapeutic action depends on the results of the experiments upon rabbits made anaemic by bleeding; experiments of this nature are, however, notoriously uncertain, on account of the great individual variations in different animals.

It is unnecessary to point out how difficult it is to obtain reliable evidence from clinical observation as to the action of drugs upon such diseases as chlorosis, tuberculosis, and general debility. In spite of the expressions of opinion by Buergi and his pupils quoted above, it still appears to us that the action of chlorophyll is still a subject of a still unsettled controversy.

The agents for phyllosan in this country are the Chlorophyll and Chemical Corporation, Ltd., 26, Coventry Street, London, W.1.

ABILITY IN CHILDREN.

In the days when schools and classes were still small an observant teacher might gain a very good knowledge of the individual capabilities of his pupils, and his judgement of ability did not always correspond with the show that a pupil might make in class work or in examinations. The advantages of the direct and intimate knowledge which the teacher of a small class or a small school possessed is impossible of attainment in modern schools, where the number of pupils runs into several hundred and a class may total forty. In addition to this, the organization necessary in large schools requires that pupils should pass from form to form or standard to standard at reasonably short intervals, so that a pupil knows many teachers but few teachers know the pupil.

To make up for the loss of the old pedagogue's intimate knowledge of the ability of a pupil many endeavours have been made to measure the mental ability of children apart from the routine knowledge to which they may have attained by diligent attendance at school. This work is inseparably associated with the names of Binet and Simon, two French investigators, whose tests have been generally accepted as the basis for a standardization of tests of mentality which can be of practical value.

The London County Council, the largest elementary educational authority of the country, has issued in a substantial volume⁷ a series of memoranda prepared by Mr. Cyril Burt, its psychologist on "mental and scholastic tests." In the first he considers in detail the Binet Simon scale and the practical methods of applying it; in the second he discusses the theoretical validity of the results of tests made with the

scale; and in the third he sets out a provisional scale of educational tests of attainments.

The school examination is a fair test of knowledge of school work, but it is a poor measure of capacity, and ignorance of school learning is no proof of defect. The argument that where attainments are meagre ability must be low will always be fallacious. Poor health, poor homes, irregular attendance at school, lack of interest in the subjects of instruction, want of will to learn them, or a higher order of diligence, of intelligence which enables the scholar to perceive their relative unimportance, are commoner causes of inability to spell or calculate than an inherent weakness of intellect or genuine defect of mind. The dull are usually backward, but the backward are not necessarily dull. To affirm the contrary would not be true, but would be nearer the truth. A high real ability does not always imply a high standard of school work. This ought to be a platitude, for history abounds in illustrations of unsuspected ability bearing rich fruit in adults who as children were reckoned indifferent scholars. Genius has laws of its own and must be left out of account, but if there were means of discovering embryo ability at an early age and giving its possessors the best advantages that our clumsy educational scheme can afford, the richness of the real capacity of the child might, it is argued, be brought to fruition without risk of such loss as must occur under the conditions at present imposed on us by pedants and doctrinaires. Similarly there are children of poor ability who struggle through the school curriculum with difficulty that may be reflected in a diminished standard of health; were their disability discovered in time a modified curriculum would enable them to develop to the best advantage any innate qualities they may possess. Some perhaps have none, but it is waste of life and happiness, so stupid as to be wicked, to cause a boy who has sympathy with plants to waste his time in learning to spell. No really good gardener can spell English. He is too observant, too much in tune with Nature. To pass judgement upon the mentality of the child is, however, part of the duty of the teacher, and he should therefore be equipped with a knowledge of modern methods of examination of mentality, which he may learn to use within his limitations.

After discussing the standard Binet-Simon scale, Mr. Burt considers the difficulties presented by its use in England, and suggests modifications to render it better adapted to our needs, for, as Dr. Simon expressed it, "La bonne traduction est elle qui d'après l'expérience laisse l'épreuve à l'âge auquel elle est placée." Some of these tests might very well have been even further modified to suit English tastes. The picture tests are taken straight from the French originals. There are three, and all are of the most melancholy description, and very foreign to our eyes. The first is a half-tone reproduction of a drawing showing a pair of unhappy-looking individuals, man and boy, hauling at a rickety handcart laden with damaged goods. It is suggestive of a retroat in Poland. It is not even definite in its drawing, for a sharp boy of 9, on being shown it, and asked what it represented, immediately pointed to the boy's head and said: "A boy with a dog's head." And sure enough the right hand of the man and the tousled head of the boy do together make a very good head of a bob-tailed sheep-dog. It turned out on inquiry that this boy had been exercising his wits with puzzle pictures, in which he was invited to "find the villain" and the like. Mr. Burt defends the transfer of these drawings, but we must admit a preference for the alternatives introduced by other workers. The line drawings for comparison of faces, and for the discovery of missing features, are equally unpleasant. All these figures have been reproduced in many textbooks on these scales, and it is time that some drawing less pathological in appearance should be shown to the children. There is no merit in melancholy ugliness. The Porteus maze tests are not altogether free from difficulty, seeing that the response to them may be very unequal: one small boy of 7 years, who has not as yet shown any special ability, did the whole series up to that supposed to be suitable for the age of 14 years with little or no hesitation, and then asked for more. We agree with Mr. Burt on the desirability for intelligent translation of these tests, and think that he might have carried his modifications a little further with advantage.

The results of the use of these tests on London children tend to show that a mental age cannot be so definitely defined as Binet seems to have supposed. There is a very considerable overlap. "To measure intelligence by the yearly stages of intellectual growth is like measuring stature by means of a tape, where the lines that separate the inches

are half defaced and the figures so broad, so blurred, and so ill centred that any one division may easily be confounded with the next."

The tests have been largely used also for the determination of mental deficiency, and it is interesting to note the results thereby obtained. The special school children (mentally defective) of London form some 1.5 per cent. of the total school population. Analysing these defective children, it is found that only one-third of them, or 0.5 per cent. of the grand total of all children, are so defective as to warrant their being classed as "institutional" cases, one third will need "supervision," and the other third are only to be reckoned defective owing to the defects of our educational system. That is a very satisfactory fact to be elicited. The more general application of these tests seems to show that there is discernible an effort, and an effort by no means sterile, to coax and coach the milder dullards of the ordinary schools to a grade more closely fitted to their actual age, so that their acquired attainment becomes greater than their inborn ability. By contrast the children who are most retarded mentally appear still more retarded educationally; and the children with superior talent are largely kept back scholastically, depressed to a stage which answers more closely to their actual years. The essays before us unmask a strong disposition to level a child's school work up or down towards the common standard for his age. That is a very grave reflection upon the effect of standardization of educational work, and one that needs much thought.

Some of the results show that the Binet-Simon scale is less a pure test of mental capacity than is sometimes thought. Mr. Burt writes: "There can be little doubt that with the Binet-Simon scale a child's mental age is a measure not only of the plane of intelligence with which he is congenitally endowed, not only of the plane of intelligence at which in the course of life and growth he has eventually arrived, it is also an index, largely if not mainly of the mass of scholastic information and skill which, in virtue of attendance more or less regular, by dint of instruction more or less effective, he has progressively accumulated in school." If this be true of children of the elementary schools, how much more will it be true of children in some smaller schools where a system of education is in practice which distinctly cultivates the powers of expression of the children, such, for example, as the system of the Parents' National Educational Union. To the children of such schools many of the tests of the scale are such as they are accustomed to practise in daily work, a condition which necessarily renders the tests valueless to them—a fact which is recognized by the author as a possible and result of the common use of these tests in schools.

The last memorandum deals with the needs and uses of scholastic tests. For the measurement of school progress there is no scheme of tests, widely used and popularly recognized, claiming the same position and enjoying the same prestige as the Binet-Simon scale for the measurement of native intelligence. In collaboration with M. Vaney, Binet and Simon did attempt what they styled a "barometer of instruction"—a set of graded exercises in reading, spelling, and arithmetic, but the tests were compiled on a rougher plan, and in any case are not suitable for transplantation to other countries. Teachers are well fitted to make their own tests, but these are necessarily unrelated to the tests of other teachers. The difficulty is found especially in attempting to compare the scholastic attainments of children in widely different parts of a great city; what is only fair in one part may be considered excellent in another. There is no true comparison, and Mr. Burt has attempted to provide a series of graded tests, suitable for measuring as scientifically as possible the attainments of individual children in all the fundamental subjects of the elementary school curriculum. The scales are confessedly tentative, but are put before the inquiring teacher as a starting point for further research, and as an indication of lines of a principle likely to prove useful. Mr. Burt, indeed, recommends that every teacher should prepare his own tests after studying this test-sheet. The questions to be contained in the tests in actual use should be left to the investigators themselves, otherwise the tests may become stale and commonplace, and, like some of the Binet-Simon tests, so popularized as to be useless for their special ends.

These memorandums include a very valuable series of investigations which cannot fail to be of great value to educationalists and those engaged in school medical inspection. The London County Council is to be congratulated on their publication.

British Medical Journal.

SATURDAY, FEBRUARY 25TH, 1922.

THE MAUDSLEY HOSPITAL FOR MENTAL DISEASE.

SIR FREDERICK MOTT, Director of the Pathological Laboratory of the Maudsley Hospital of the London County Council, is retiring under the old rule, but the Council has arranged to retain his services until October next. He has held the appointment with great distinction since the hospital was erected, combining with its duties those of pathologist to the Council's asylums. The County Council is taking steps to appoint a medical superintendent to the hospital at a salary of £600 a year, with temporary additions on the Civil Service scale, and the right to engage in private practice as a consultant, subject to certain conditions, one of which will probably be that he shall reside in the neighbourhood of the hospital. So far as our information goes, no steps have yet been taken to decide on the staff which will be needed, but it is obvious that the objects with which the hospital was founded cannot be attained through the work of any single individual acting as medical superintendent.

We remember how in 1908, in a report on the arrangements made with Dr. Maudsley, the Chairman of the Asylums Committee spoke of the hope that the hospital would prove of great value in the dissemination of knowledge of mental disease, and in the provision of systematic instruction in methods of treatment. This hope has, indeed, partly been realized by the institution of courses for the diploma in psychological medicine, in the conduct of which Sir Frederick Mott has gathered about him some of the most distinguished exponents of the subject. The courses have been extremely well attended; but two things have somewhat militated against their complete success. The first is that, as there were no patients in the hospital, clinical instruction had to be given elsewhere; and the second, that the University of London has not shown the faintest interest in the matter. The chairman, in the report from which we have already quoted, referred to the advantages which would flow from the hospital being in close touch with the university, the general hospitals, and the medical schools. It was not, he truly said, to the advantage of the profession or the public that the study of insanity should to so great an extent remain an isolated branch of medical research. The belief was expressed that were this defect remedied, a closer acquaintance with the peculiarities of mental and nervous diseases would become more common, and many cases of incipient insanity which now find their way ultimately to the workhouse or to the asylum would by suitable treatment in the earlier and more hopeful stages recover without needing confinement in an institution. The need for a central pathological laboratory was also mentioned.

These are admirable sentiments, and a pathological laboratory exists, but the story of its dealings with the gift made to it some fourteen years ago by the late Dr. Henry Maudsley is not altogether creditable to the London County Council. There was, in the first place, an unexplained and most regrettable delay in finding a site and building the hospital. Its erection proceeded by slow degrees, and it was barely complete when early in the war it was taken over by the War Office for soldiers suffering from mental and nervous disorders. Though the hospital was given up by the military

authorities some fifteen months ago, it is, we find, still unoccupied, yet the demand for the accommodation and treatment it could afford to civilian patients is pressing—so pressing, indeed, that we can hardly believe the suggestion, which nevertheless is being made, that it is being kept empty to save expense. No doubt sooner or later it will be taken into use, and the decision to appoint a medical superintendent is an indication of this intention.

But the purpose Dr. Henry Maudsley had in view was not to establish another asylum. His purpose was to set up an acute mental hospital which would serve as a model to other localities, and be a centre of investigation in both functional and organic diseases of the brain and spinal cord. To this end it is necessary to have a suitable hospital in a convenient locality, with a laboratory well equipped and of adequate size attached to it. These have now been provided. But for the intensive study of acute mental disorder, and for pathological routine work, to say nothing of research, a large staff is necessary. If we look abroad we find that the institute at Zurich has a medical staff of eleven—the Director, Professor Bleuler, two senior medical officers, five assistant medical officers, two voluntary physicians, and one pathologist. It has 400 beds; the number of admissions is about 750 annually. Of the beds, 250 are occupied by chronic patients, for whom two medical officers, in addition to the Director, would probably suffice. But it has 150 beds for acute cases, and these have a rapidly changing population; it is with them that the remaining officers are fully occupied—so fully, indeed, that in practice the pathologist has had to be taken away for clinical work, and in fact does no pathology. At Utrecht there is a mental hospital of about the same size under the direction of Professor Winkler, one of the most distinguished neurologists in Europe. He has a salary of £1,000 a year, a good house, and the right to private practice. Under him are a staff of five medical officers, and eight assistants in the laboratory. At the Psychiatric Clinic at Munich the Director, Professor Kraepelin, has working with him two senior physicians, four senior assistant physicians, four junior assistant physicians, five voluntary physicians, and three other officers recently qualified, whose duties are similar to those discharged by the clinical assistants working in the departments of general hospitals in England. The Munich clinic has 160 beds; the number of patients admitted annually is about 2,000. Again, at Cologne, Professor Aschaffenburg, the Director of the Psychiatric Clinic, has under him one senior physician, two assistant physicians, and a fluctuating number of voluntary physicians and newly qualified men.

The Maudsley Hospital, as we have said, possesses good laboratories, and it is in the direction of them that Sir Frederick Mott has been chiefly occupied. But we have shown how large a staff is considered necessary for the clinical study and treatment of acute mental cases. We still hope that the London County Council will rise to the height of its responsibilities, and organize the staff of the Maudsley Hospital on a liberal basis, both as to the number of the staff and their salaries. We are quite certain that its reward would be great, and that in the long run, even from the financial point of view, the ratepayers' pockets would be saved.

MILD SMALL-POX AND VACCINATION.

The county medical officer of Lancashire (Dr. Butterworth) and his staff are to be congratulated on the very full, painstaking, and well-balanced report they have prepared on an outbreak of small-pox in Middleton in 1920. Indeed it is difficult to think of any aspect of the subject with which they have failed to deal, and that is important, because the epidemic was of so mild a type

that a less thorough investigation and record might well have been thought sufficient. The administrative measures adopted were of the usual character, including hospital isolation, disinfection, vaccination and revaccination, and surveillance of contacts and common lodging-houses.

The total number of cases was 83, and there was not a single death amongst either vaccinated or unvaccinated. Yet vaccination had abundant opportunity of demonstrating its value in protecting against attack. None of the 83 cases had been vaccinated or revaccinated within a period beginning seven years before and ending ten days before the onset of the disease. No child under 10 who had been vaccinated in infancy developed the disease, whereas 26 unvaccinated in this age period contracted it. Seven females were attacked between 20 and 40 years, but not a single male, and it is pointed out that this age period included ex-service men vaccinated during the war. Living in infected houses there were 175 persons who escaped the disease, and every one of them had been vaccinated either before or during the epidemic. The number of affected houses was forty-five, and a special investigation of vaccinal conditions was made in sixteen of these, containing 112 inmates, with the result that of 19 unvaccinated persons only one escaped attack; of 12 vaccinated over seven years ago, 6 escaped and 6 were attacked; of 8 vaccinated within seven years, all escaped; of 38 primarily vaccinated over seven years ago and revaccinated since contact, 37 escaped and one was attacked; of 34 primarily vaccinated subsequent to contact, 28 escaped and 6 were attacked; one person, protected both by primary vaccination and by small-pox in a previous epidemic, escaped. These figures go to demonstrate the value of vaccination even where there are no fatalities among the unvaccinated.

During the epidemic 4,410 vaccinations and revaccinations were performed, and if allowance be made for infant vaccinations by public vaccinators during the last seven years, and for vaccinations during war service, it is calculated that the total of recently vaccinated persons in Middleton at the end of the epidemic was approximately 33.9 per cent. of the population. Dr. Butterworth calls attention to the importance, in a vaccination campaign during small-pox, of securing the protection of contacts before dealing with others offering themselves for the operation, in order to prevent, as far as possible, dangerous delay in respect of contacts. Details are given of the precautions very successfully taken to prevent septic complications following vaccination and revaccination.

In discussing concurrent vaccinia and variola, attention is called to the mild type of the disease, and the interesting suggestion is made "that the quantity and quality of the small-pox virus initiating the infection influenced the question of the day up to which vaccination would be successful," and that "the cases in which vaccination failed probably had a more massive infection with the small-pox virus, or a less massive insertion of vaccine virus, than those in which the vaccination was successful." This proposition is very relevant to what has often been puzzling with regard to observed differences in the time which vaccination must have in order to overtake small-pox infection, so as to get home first in the race between variola and vaccinia. It need not cause surprise that vaccinia can sometimes be successfully cultivated locally in the earliest days of a variolous eruption. Cow small-pox and human small-pox are so nearly allied that they can grow together until one or other makes the subject immune to infection. As soon as that happens a further immediate attempt at vaccination will fail. This was so found in the Middleton epidemic.

A striking feature of the epidemic was the invasion of the largest school in Middleton. It began with a missed case in an unvaccinated child. Of the total number of cases in the borough 19 were in the school, and they were all notified within a period of nine days. All these were unvaccinated excepting two who had been vaccinated in infancy. One of the two was a teacher, aged 53, the other a child of 10. The vaccination history of 419 of the school children was investigated, and only 156 had been vaccinated in infancy. Of these 33 were revaccinated during the epidemic; 95 others were now vaccinated for the first time, whilst 168 remained unvaccinated. The school was closed for eleven weeks, largely because the attendance was much diminished, more than half being absentees who had to be kept under observation at home. The fact may be recalled that in the great Gloucester epidemic school children were a main cause of the spread of the disease throughout that city. A very important difference is, however, that the type of disease there was much more severe than in Middleton. Indeed, though various missed cases occurred in Middleton, we may assume that the total infective material must have been very small as compared with what would exist in a severe epidemic with abundant eruption. The risk from the missed cases may have been much more than counterbalanced by the low degree of infectivity of missed and recognized cases alike. In addition, there was the invaluable work of Dr. Butterworth and his assistants, several of whom were specially detailed for duty in Middleton, whilst the Ministry of Health, through Dr. Reece, gave valuable help during the epidemic. Such concentration of effort has become practicable only in recent times, and demonstrates the advantage of the county system of local government.

The report ends with a series of fifteen conclusions, of which the last is: "That the suppression of the epidemic was due to vaccination, revaccination, supervision of contacts, and the discovery of missed cases." There follows in an appendix a series of charts and diagrams, most of them devoted to the very useful purpose of showing the distribution of the rash both in small-pox and in chicken-pox. The origin of the outbreak is left in doubt. The hypothesis is fully discussed that it was due to infected cotton brought to local mills from America, where the type of small-pox is now commonly very mild, but Dr. Butterworth has cautiously reached the opinion that the theory is unproved for Middleton. In the end he adopts the somewhat trite conclusion, "that the most likely origin of the epidemic was a missed case." That is really another way of saying that the source could not be discovered.

It should be noted, finally, that the whole of Lancashire is indebted to its county medical officer for his masterly handling of the outbreak, occurring as it did in a town closely surrounded by great urban communities, such as Manchester, Rochdale, Heywood, Chadderton, Royton, Prestwich; extension to which might have involved a tremendously widespread epidemic.

THORACIC SURGERY AND SUBPHRENIC ABSCCESS.

THE benefits which surgery derived from Henry V's campaign in France have been made very clear to us by the historical researches of Sir D'Arcy Power. In our own time the lessons learnt in battle surgery are bearing fruit in even more vital ways.

The timid and often only half-curative pre-war operations on the chest are giving place to bolder and better devised measures, which are justified by the brilliant progress made under stress of dire necessity during the war. Of all the books on battle surgery published during

the war, the great classic was Duval's book¹ on war wounds of the lung. Its influence is likely to spread far beyond the limits implied in its title. Dr. Ambrose Lockwood, writing from the Mayo clinic on "Developments and possibilities of thoracic surgery," provides a striking illustration of this influence. Although Maccewen more than twenty years ago had shown that the thorax might be opened with as little ceremony as the abdomen itself, the generality of surgeons paid no heed to his teaching. The thorax remained a region to be approached with dread, and unhandy pressure chambers were deemed essential to the safe performance of thoracotomy. As Lockwood rightly says, "When it was realized" (as the result of the war and the influenza epidemic) "that the thorax could be opened and explored and the contents handled with as little risk as that attending the manipulation of the abdominal viscera, perfection of technique was all that remained to bring thoracic surgery to the standard it has attained to-day." Lockwood's contribution to this perfection of surgical technique under the most difficult forward-area conditions was one of the notable achievements of the war, although he would be the first to acknowledge the encouragement and practical help given him by his D.M.S. (Sir Menus O'Keefe) and his commanding officer (Major R. J. C. Thompson).

On his return to the surgery of civil life Lockwood has applied his experience to good purpose in the operative treatment of thoracic conditions as met with in everyday practice. Empyema, lung abscess, bronchiectasis, foreign bodies, traumatic lesions, tumours of the thoracic wall, enlarged thymus, purulent pericarditis, subdiaphragmatic abscess, hernia of the diaphragm, and intrathoracic neoplasms are among the conditions to which improved surgical technique will bring prospects of sounder cure or greater alleviation. He suggests that splenectomy and operations on the cardiac end of the stomach may be performed more easily through a combined abdomino-thoracic incision. In his recent paper Lockwood does not devote much space to the problems of diagnosis, except that he insists on the immense value of x-ray examinations. The day is probably not far distant when a physical examination of the chest made without x rays will be regarded as no more complete than if auscultation itself had been omitted. Lockwood is an ardent advocate of local and paravertebral anaesthesia rather than a general anaesthetic for thoracic surgery, and his preference is right well founded. His description of the technique of the actual operation for thoracotomy is lucid and admirable. His remarks on the necessity for hermetically closing the chest at the end of the operation, for repeated aspiration afterwards, and his observations on the expansion of the lung deserve the closest attention.

In another paper² Lockwood discusses subdiaphragmatic abscess in all its bearings. The description of the anatomy of the under surface of the diaphragm is clear and complete, and follows in the main Barnard's anatomical account published in 1908. The etiology, symptoms, course, and complications are excellently set forth. The important part played by the lymphatics in determining the localization of subphrenic suppuration is emphasized; so, too, is the indispensability of x-ray examination in diagnosis. The extreme variations in the leucocyte count show that too much reliance must not be placed on leucocytosis as a diagnostic aid. The operation advocated is devised particularly for abscesses located on the right side. Rib resection is avoided. When the incision has been made the edges of the skin are undermined, the parietal pleura, with the diaphragm adherent to it, is separated from the rib above the incision and from the rib below, and,

after forcing the interspace widely enough open to admit the hand, the cut edge of the muscle with the pleura is sutured to the diaphragm. The diaphragm is brought out as far as possible through the interspace and the edges of the skin are sutured to the diaphragm so as to shut off completely the intermuscular and fascial planes. Whenever possible the patient is sent back to bed for twenty-four to thirty-six hours and the diaphragm incised at a second operation. If a two-stage operation is inadvisable the diaphragm can, as a rule, safely be opened after smearing the suture line with vaseline. The after-treatment is of no less importance. A two-way drain is left in the abscess cavity and 1 oz. of saline is passed through the tube three times a day to clear it for drainage. On the sixth or eighth day the drain and packing are removed. The cavity is swabbed out with saline and inspected with a lighted retractor, and the wound is packed with glycerin and saline. A two-way catheter is left in position for drainage until the cavity is closed. The advantages of this method are summarized in series of thoughtful conclusions.

There is no doubt that thoracic and abdomino-thoracic surgery are on the threshold of advances long overdue. A clear indication of this was given by Professor G. E. Gask in his admirable Lettsomian Lectures before the Medical Society of London last year. No longer will textbooks be justified in summing up the surgical treatment of empyema as consisting in the evacuation of the pus and the provision of free drainage. Estlander's mutilating operation will, it is to be hoped, be abandoned. Surgeons embarking on the newer methods must bear in mind, however, that modern thoracic surgery demands uncommonly thorough mastery of technique and well-nigh fanatical asepsis.

THE PENSIONS ORTHOPAEDIC HOSPITAL, SHEPHERD'S BUSH.

In February, 1916, thanks chiefly to the prescience and energy of Sir Robert Jones, the War Office opened the Military Orthopaedic Hospital at Shepherd's Bush in the buildings of the Hammersmith Infirmary. To these buildings a number of others were added, until this institution became a model of what such a hospital should be, containing within itself every ancillary department that is necessary for the treatment of the deformities and disabilities consequent upon war injuries. The work was continued, and still goes on with unabated vigour and success under the Ministry of Pensions, and it must be many years before this and the similar institutions in the provinces cease to find occupation. When it is proposed—as paragraphs and letters in the daily press and questions in Parliament have disclosed to us—that such an institution should be removed to a distant site it might naturally be supposed that the only valid reason for such a proposal must be that the treatment of disabled pensioners would thereby be improved. But the letter of Mr. McCrae Aitken, which we print on another page, shows with convincing clearness that the proposed change is not likely to produce any such result, but that, on the contrary, the removal and separation of the in-patient and the out-patient departments must inevitably lead to delay, discomfort, and hardship for the patients, and, by impairing the efficiency of treatment, result in decreasing the proportion of pensioners who will be restored to conditions which will enable them once more to earn their daily bread. It must, we think, come as a painful surprise to our readers that the reason alleged for the removal is not that the patients will benefit, but that a problematical saving of a few thousands a year is expected to be made by the changes. Were there even a reasonable probability of this saving, it should count as nothing in the balance against the preponderant interest of the men injured in the defence of their country and of the sacred cause of freedom. We think, however,

¹ Duval: War Wounds of the Lung. Wright, 1918.

² Surgery, Gynecology, and Obstetrics, 1921, p. 502.

that it is more than doubtful if any saving would accrue to the country as a whole; for the resumption of the infirmary by the guardians must involve considerable capital expenditure besides a great increase in the cost of maintenance of the sick poor who are now efficiently provided for elsewhere, while large sums would have to be expended by the Ministry of Pensions to render the Richmond hut hospital and the out-patient clinic efficient. The visiting staff of the hospital consists of surgeons, some of whom had great knowledge of orthopaedic work before the war, and all of whom have now acquired unequalled experience in the treatment of the difficult problems presented by the injuries and mutilations of modern warfare. They are now fully occupied during the time allotted to their visits, which amount to many hours a week. Yet it is clear that if they are to do part of their work some six miles further from London in order to treat in-patients, besides paying visits to an out-patient centre or centres, they must spend so much time in travelling that they will have less to devote to their actual work. Continuity of treatment is essential in these cases, and it is of the first importance that the surgeon who operates upon the case and treats him as an in-patient should continue to treat him as an out-patient. Therefore it will be necessary for the same surgeons to visit both the out-patient centres and the wards. Leaving aside for the moment the all-important question whether treatment can be as efficient as under present conditions—we have no hesitation in asserting that it cannot—on the lower ground of finance alone it is clear that the prolongation of the time of treatment which must inevitably result from such an arrangement will entail in the case of each man an increased expenditure in maintenance and in treatment allowances which is almost sure to swallow up any possible saving which might be made by this deplorable proposal which cannot fail to diminish the efficiency of the treatment of men who have earned the right to the best. The medical profession will be unanimous in condemning the proposed changes, which might probably be avoided if negotiations were reopened in a conciliatory spirit on both sides, so that a fair rental could be agreed upon.

SPIRITUAL HEALING.

ON January 14th (p. 72) we called attention to a resolution of the Lambeth Conference in 1920 requesting the Archbishop of Canterbury to appoint a committee "to consider and report as early as possible upon the use with prayer of the laying-on of hands, of the unction of the sick, and other spiritual means of healing." At the meeting of the Upper House of Convocation on February 15th the Archbishop of Canterbury announced that after consultation he had appointed the following to serve on the committee: The Bishop of Oxford (chairman), Sir Clifford Allbutt, the Rev. Harold Anson, the Rev. E. J. Bicknell, Dr. William Brown, the Bishop of St. Albans, Bishop Chandler, the Bishop of St. Edmundsbury, the Bishop of Southwark, the Dean of Wells, Dr. J. A. Hadfield, Sir R. Armstrong-Jones, Canon A. J. Mason, the Rev. J. O. F. Murray, Master of Selwyn College, Mr. W. H. B. Rivers, F.R.S., Canon Streeter, the Rev. W. B. Trevelyan, and Dr. Jane Walker. Among the questions submitted to the committee were the following: Are we justified in assuming that there has been "the ministry of healing" in the Church? If so, what was its precise character? What qualifications and tests were required to become a minister of healing? Did it supplement or disregard the service of the physician—that is to say, were gifts of healing distinct and independent of the gifts of healing by medicine and surgery? If, without a technical ministry, there has been the habitual practice of laying-on of hands with prayer, with or without unction, has this been a method of healing different in kind from other methods of treatment? Even if there has been no ministry of healing, is the Church called upon, in the light of modern research and discovery, to direct the knowledge gained and to use it in her ministrations? It will be seen that much of the work proposed to the committee is of the

nature of historical research. Therein its object differs from the task upon which Bishop Ryle's Committee on Spiritual Healing was engaged before the war. That committee, dealing with modern methods of spiritual healing, expressed the belief that "Divine power is exercised in conformity with, and through the operation of, natural laws." It considered that "spiritual ministration should be recognized equally with medical ministration as carrying God's blessing to the sick." But the committee was of opinion that the "physical results of what is called faith, or spiritual healing, do not prove on investigation to be different from those of mental healing, or healing by suggestion." The conclusion was that spiritual healing, like all treatment by suggestion, can be expected to be permanently effective only in cases of what are generally termed "functional" disorders; but that persons suffering from organic disease can be greatly comforted and relieved, and even physically benefited, by spiritual ministrations, which appeal to the spiritual nature, reinforce the spiritual powers, and may thus contribute to the success of physical treatment by the medical practitioner. The report of Bishop Ryle's Committee ended by deprecating strongly the independent treatment of disease by irresponsible and unqualified persons. It may be doubted whether the new committee will be able to go much beyond those very sane and reasonable findings—a distinguished authority has called them platitudinous.

THE INDUSTRIAL FATIGUE RESEARCH BOARD.

IN the second annual report of the Industrial Fatigue Research Board, which has just been issued, we find a comprehensive summary of the chief results obtained by the Board since its inception some three years ago. These results have been published in a series of sixteen reports, which really represent the output of the Board's investigators over a period of about two years, for there is necessarily a considerable delay before the results of the inquiries reach the stage when they are ready for publication. If any critic had doubts as to the value of the Board's work, and the importance of its further development on the lines laid down in this report, we think that such doubts would speedily be laid to rest by an impartial study of its pages. They contain a solid body of information which is of direct value to employers of labour, and to welfare workers and factory inspectors; the practical application of this information to the remedy of adverse industrial conditions would produce a very real improvement in the health and efficiency of the workers. In the analysis of published work with which the report opens the various tests of efficiency and fatigue employed are briefly described, and then a more detailed account is given of the results obtained in various industries concerning output in relation to hours of labour and the duration of work spells and rest pauses. A subsequent section of the report deals with the impersonal physical conditions of the worker's environment, such as temperature, humidity, ventilation, and lighting, and the effects of these conditions on efficiency. Personal factors, such as vocational selection and guidance, time and motion study, and the effects of such conditions as seating and clothing, are treated in considerable detail, whilst a shorter section deals with such matters as organization and the relative importance of human and mechanical factors in efficiency. Most of the sections are illustrated by diagrams reproduced from the published reports of the Board, and they show at a glance the hourly and daily variations of output observed under various conditions, the effect of regular rest pauses on output, the improvement of output caused by more adequate lighting and by better ventilation, and the value of certain psycho-physiological tests in measuring the skill of compositors. The future of the Board seems full of promise, for, in addition to the investigations already made in certain branches of the textile, iron and steel, and boot and shoe industries, others are now in progress in the laundry and the pottery industries, whilst application has been made to the Board by various trade boards and research associations for the institution of inquiries into several other important industries.

CARBON MONOXIDE IN LIGHTING GAS.

LAST autumn we found it necessary to comment very unfavourably on the report (which had just been issued) of a Departmental Committee on the dangers from carbon monoxide in lighting gas. We pointed out that this committee had greatly underestimated the risks involved in increasing the percentage of carbon monoxide in lighting gas, and that the report was likely to mislead the gas industry very seriously. The facts on which our criticisms were based will be found set out in our articles published on September 10th (p. 411) and October 1st (p. 534), 1921. During the present winter cases of poisoning by lighting gas have been frequent, and the need for safeguards against the increasing risks of poisoning by carbon monoxide has recently been pointed out in articles and correspondence in the newspapers. As a consequence, doubtless, of this increasing frequency of poisoning by lighting gas, the Board of Trade has now issued an order that no lighting gas shall be distributed unless it has a pungent smell. We must point out, however, that the gas distributed in public supplies has and always has had a pungent smell. The order has thus no bearing whatever on the existing dangers. The frequency of poisoning by lighting gas has begun to exceed the limit of what public opinion will tolerate, and no further comment is now needed on the report of the Departmental Committee. As we have pointed out, the great increase in frequency is due to the increased percentage of carbon monoxide in the gas. It may be possible, by various precautions, to avoid these risks; but on the nature of these precautions the report of the late committee threw no light. It is unfortunate that leading representatives of the gas companies are now screening themselves behind the report instead of taking action to diminish the danger to the public. The situation can hardly remain as it is, and requires careful consideration by medical officers of health throughout the kingdom. It appears that in view of the terms of the late committee's report no Government department has now any power of interfering with the discretion of gas companies as regards the proportion of carbon monoxide in the gas they supply. On the other hand, we are confident that gas companies are particularly anxious to avoid exposing the public to avoidable risks of poisoning, and will be ready to take suitable action in response to well-considered representations from medical officers of health. If, however, the matter is not dealt with satisfactorily in this or some other way, there must be no hesitation in calling for legislation limiting the percentage of carbon monoxide in public supplies of lighting gas. The mistakes of a departmental committee cannot be allowed to stand in the way of public safety.

RADIOLOGY AND PHYSICS.

THE third Mackenzie Davidson memorial lecture was delivered at the Royal Society of Medicine on February 17th, when Major G. W. C. Kaye, D.Sc., was the lecturer, and described the ever-growing importance of physics to the radiologist. The appreciation of the physicist by the medical worker in this country, he said, was a plant of tender years. The average medical student, with an eye on the forthcoming examination, was prone to dislike and distrust physics. It was not sufficiently brought home to the student that a knowledge of physics, so far from trammelling him, would liberate him from many false notions. Major Kaye devoted most of his lecture to the physics of the x ray. Not everybody knew that x rays played a material part in nature. The sun was an x -ray bulb, but such x rays as escaped towards the earth were almost wholly arrested by the upper layers of the atmosphere, which accounted for the fact that the natural ionization of the air increased with altitude. No doubt x rays played a part in atmospheric electricity, and they might be held responsible for some of the vagaries encountered in wireless telegraphy. Until recently a gap of four octaves existed between the shortest ultra-violet ray known to spectroscopic science and the longest x ray, but within the last few weeks, as the result of experiments by indirect

photo-electric methods on the part of a number of workers, both in England and America, it had been discovered that the continuity was complete, and that the x rays immediately followed the ultra-violet, or even overlapped into the ultra-violet region. The ultra-violet extended from 3,600 to 200 Angstrom units, the x rays from 500 to 0.06 units, and the gamma rays of radium from 1.4 further into the infinitesimal. The wave-length of the gamma rays was something like one 10,000 millionth part of a centimetre, and at the other extremity of the scale were the Hertizian waves with a length of several miles. There were sixteen octaves of x rays, and as yet the radiologist had turned only three of them to account. The output of x rays from a tube was proportional to the atomic weight of the metal used as target, to the current passing through the tube, and to the exciting voltage, which last was by far the most important thing for the radiologist to measure. Many new problems of interest awaited radiology when still higher voltages were made possible. Recently there had come news from America that Dr. Coolidge had succeeded in building a transformer which was capable of yielding a million volts. The problem of designing x -ray apparatus to "stand up" to such voltages was not a light one. In conclusion the lecturer dealt with the subject of x -ray protection and the labour of the Protection Committee recently established as a result of the conjoint effort of interested societies. It had been his lot to inspect the conditions obtaining in the radiological departments at a number of hospitals, and he found matters very unsatisfactory. The protection for the operator was lamentable in its inadequacy. He had taken with him a delicate electroscope, with the object of exploring the scattered radiation in different parts of the x -ray room, and had found that this radiation was far beyond the capacity of the instrument to register. The investigators had to content themselves with the relative ease with which they could see the bones of the hand on a fluorescent screen carried about the room! Ventilation was of importance second only to the actual limitation of the issuing beam, yet many hospitals appeared to regard the radiologist as akin to the mole or earthworm, and packed him away in the basement, not far from the furnaces. The high-tension system also was not as it should be, and sometimes the coronal brush discharge on the wires resembled a bonfire night at the Crystal Palace. Generous recognition should be given to the action of x -ray apparatus manufacturers for their assistance in the matter of protection. It was a very wise precaution to secure a certificate from the National Physical Laboratory as to the efficiency of the lead-glass and lead-rubber used for protection, because the protective value of these materials varied within very wide limits.

THE TEETH OF THE NATION

PROFESSOR W. D. HALLIBURTON, F.R.S., who is chairman of the Committee on the Causes of Dental Decay appointed by the Medical Research Council, gave a lecture at the Royal Institution on the evening of Friday, February 10th, on the teeth of the nation. A number of skulls on the lecture table suggested the antiquity of dental mischief, though they included a rarity in the shape of a modern adult skull with perfect teeth. From the mouth of Jacques we had learned that the last scene of all which ends man's strange, eventful history was marked by toothlessness; and a much earlier oracle, the writer of the book of Ecclesiastes, spoke of old age as a time when "the grinders cease because they are few." The idea, based on some neolithic skulls with perfect dentition, that remotest man was free from this common ill, had been upset by the discovery of the Rhodesian skull, which exhibited a typical form of dental caries. The fossil mastodon also was said to show evidences of this trouble, but on this point the lecturer was sceptical. He reminded his audience that the teeth were a living portion of the body, and were affected by constitutional influences far below the surface, and in their turn, when unhealthy, were the source of many evils, affecting not only the alimentary canal, but leading to septicaemia and

rheumatoid affections. He also pointed out that the foundation even of the second and permanent set was laid in intra-uterine life, so that the dental question was in its beginning a question of pre-natal and infant care. The consumption of overmuch sugar was to be avoided because it was converted into lactic acid, which was destructive of the protecting enamel. It might be urged against this prohibition that the workers in cane-sugar plantations, whose mouths were full of sugar from morning to night, suffered comparatively little from dental troubles; but cane-sugar excited a flow of saliva which washed away the offending material, and this did not apply to the same extent to glucose and the sugars commonly used in sweets. He uttered a special warning against allowing children to go to bed with sweets in their mouths, for in the night, when the flow of saliva was diminished, this sticky paste had its opportunity to foster dental decay. Professor Halliburton gave a vivid popular description of the formation of the teeth, likening the process to the operations in building, especially sculpturing and plastering, and showed some photomicrographs by Mr. Howard Mummery to demonstrate a matter which dentists had been slow to recognize, that the nerve fibres penetrated into the dentinal tubules. It was natural for the human mind to associate strength with solidity, but nature might have shown us quite early that there was a superior form of building to that exemplified in the castle wall—namely, slender lattice work, which might prove as resistant as solid masonry, and was much more economical. It was on that principle that bone and teeth were built, and also, on a larger scale, what might be called the teeth of the earth, in the shape of the cliffs jutting into the sea. The analogy between the two might be carried further still, for the basaltic columns found on the Island of Staffa, at the Giant's Causeway and elsewhere, were as a rule hexagonal, and so, when examined under the microscope, were the prisms of the enamel or adamant which fitted into corresponding depressions on the surface of the dentine. One of the skulls exhibited by the lecturer, from the collection at the Royal College of Surgeons, was that of some unknown soldier, found in France, and he pointed out the narrowness of palate and depth of arch. About one modern skull in four exhibited this curious down-growth of the alveolar process, which accounted for the long narrow face so frequently seen among intellectual men.

A DIPLOMA IN TUBERCULOSIS.

PROPOSALS to set up a diploma in tuberculosis, to serve as some evidence of the competency of candidates for the post of tuberculosis officer, have been considered by several universities and licensing bodies, but hitherto all have hesitated, mainly because the policy of establishing a diploma in any particular disease was felt to be of doubtful wisdom. The University of Wales has now taken the plunge, and we publish elsewhere a letter from Professor S. Lyle Cummins, explaining the reasons which have moved that university to set up a Tuberculous Diseases Diploma. The first is that the number of appointments for whole-time tuberculosis work is already large and is likely to increase; the second is that the diploma would provide young medical men with evidence that the holder had devoted a period to the study of the disease; the third is the importance of encouraging the study of the disease as a whole, including its surgical manifestations; and the fourth is the belief that preventive measures are likely to be based on sounder lines if greater account is taken of tuberculosis as a general rather than a local disease. The curriculum and examinations, details of which are given at p. 333, will suffice to afford adequate evidence of the holder's technical competence, and the Welsh National School at Cardiff has arranged a special course of instruction, both theoretical and practical. The contracted title of the diploma is to be T.D.D., and there were, no doubt, sufficient reasons for avoiding the shorter form, D.T., while there is not much fear that the holders will be supposed to be a new kind of Doctors of Divinity. The multiplication of diplomas in special

subjects during recent years has been remarkable. Oxford gives a diploma in ophthalmology, other universities give diplomas in tropical medicine and hygiene, in psychological medicine, in medical radiology and electricity, and Manchester grants special certificates in factory medicine and in school hygiene. The number of letters which a medical man may now be able to put after his name has become very large, and we suggest discretion in their employment. To put oneself down as M.D., M.R.C.S., L.R.C.P., L.M.S.S.A., D.O., D.T.M. and H., D.P.M., D.M.R. and E., and T.D.D. would be a trifle absurd; and then there is the D.P.H., which, however, may be entered on the *Medical Register*.

AN HONOUR TO MEDICAL OFFICERS OF HEALTH.

THE President and Council of the Society of Medical Officers of Health were entertained by the Lord Mayor of London to luncheon at the Guildhall on February 17th. The principal guest was Sir Alfred Mond, who, in proposing the toast of the Society, said that as Minister of Health he was somewhat in the position of a godfather to the medical officers of health in the country, and watched their proceedings with the greatest sympathy. It was of the highest importance that the best men should be attached to the public health service, and local authorities could not expect to get first-class service at third-class salaries. This was a time of great anxiety to one holding his position, but he did not intend that the work should fall back. Though there was an extraordinary strain on the financial resources of the country at the moment, and everyone was anxious to co-operate in effecting economies, nothing must be done in that direction which would prevent the country from securing satisfactory results. Even in these days of retrenchment it would be false economy to employ a man who was not up to his job, in order to save a small outlay on his salary. Dr. Howarth, M.O.H. for the City of London, in responding, said that the forward policy of the City of London had done much to bring the public health service up to its present state of efficiency, which was so high that this country was everywhere looked up to in matters concerning the prevention of disease. A vote of thanks to the Lord Mayor, proposed by Lieut.-Colonel Fremantle, M.P., was suitably acknowledged.

COMMITTEE ON BIOLOGICAL ACTIONS OF LIGHT.

THE Medical Research Council has appointed a Committee to advise it upon the promotion of researches into the biological actions of light, with a view to obtaining better knowledge of the actions of sunlight and other forms of light upon the human body in health or disease. The Chairman of the Committee is Professor W. M. Bayliss, F.R.S., and the other members are Mr. J. E. Barnard, Dr. H. H. Dale, F.R.S., Captain S. R. Douglas (late I.M.S.), Sir Henry Ganvain, M.D., Dr. Leonard Hill, F.R.S., and Dr. J. H. Sequeira. The Secretary is Mr. Edgar Schuster, D.Sc.

HOSPITALS AND PAYING PATIENTS.

THE report of the Council to the Representative Meeting on the organization of voluntary hospitals, particularly as affected by the reception of patients for whom payment is made, will be found in the SUPPLEMENT for this week. It will eventually form part of the Annual Report of Council, but is printed thus early in order that it may be fully considered by the Divisions in time to allow any amendments they desire to be considered by the Council, which will deal with them in a further report. The Secretaries of Divisions have been asked to call special meetings to consider this report, which in its final form will be discussed at the Annual Representative Meeting at Glasgow next July. If then adopted it will become the policy of the Association on this matter. The report was drafted by the Hospitals Committee, and was considered at length by the Council at its meeting on February 15th. A report of other proceedings of the Council on this occasion will also be found in this week's SUPPLEMENT (p. 49).

AN INSTITUTE OF HYGIENE IN LONDON.

It has been known for some time that the Rockefeller Foundation has been seriously considering the recommendation for the establishment of an Institute of Hygiene, contained in the Report of the Post-Graduate Medical Committee published last May (the Athlone Committee). The recommendation was that an Institute of State Medicine should be established in London with well equipped laboratories and an efficient staff. It was further recommended that the Institute should also provide instruction in other directions, including courses in forensic medicine, toxicology, and industrial medicine.

These recommendations were considered by an expert committee, with the Minister of Health as chairman. In view of the difficulty at present of financing the scheme, the whole case was put before the Rockefeller Foundation as one in which they might think it well to co-operate in the general interest of progress in public health here and abroad.

The Minister of Health has announced that the Rockefeller Foundation have offered to provide a sum of two million dollars towards the cost of building and equipping an Institute or School of Hygiene in London, on the understanding that the British Government accept the responsibility of providing for the staffing and maintenance of the school when it is established. This generous offer has been accepted by the Minister of Health on behalf of the Government.

Hygiene, like other departments of medicine, knows no boundaries. In that sense this gift is made for the benefit of international medicine, but this country is grateful to the Rockefeller Foundation that it should have been selected. The Athlone Committee estimated that the cost of maintaining an Institute of State Medicine would be about £10,000 a year. The scale on which the Rockefeller gift will make it possible to establish the Institute of Hygiene (it amounts to the present rate of exchange to over £400,000) will call for larger expenditure for staff and maintenance; we have heard it estimated at £25,000 a year. Those familiar with the Athlone report will remember that it proposed to associate the Institute with the University of London. This recommendation, it would appear, is not to be carried out, and the annual expenditure will therefore not come out of moneys at the disposal of the University Grants Committee, but will be met by a special vote of Parliament. The intention is, we believe, that the Institute of Hygiene shall be administered by a mixed committee, representing the various bodies interested, for it is to be remembered that London already possesses certain important elements of an institute of hygiene.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

The Orthopaedic Hospital at Shepherd's Bush.

MR. TRYON informed Mr. A. Herbert, on February 15th, that it was proposed to give up the hospital at Shepherd's Bush, which has been specially equipped for orthopaedic surgical treatment at a cost of £16,000 by the Red Cross Society. The equipment would be moved from the present institution and installed elsewhere for the continued treatment of pensioners. On another question by Mr. Wilson, Mr. Macpherson said that the transfer was to be to the South African Butment Hospital at Richmond. He had received urgent representations from the guardians of Hammer Smith that the administration of parochial relief was seriously impeded by the continued use by the Pensions Ministry of this institution, which was formerly the workhouse and infirmary of the parish, and they were willing only to assent to extended aid in return for a greatly increased rental, which would not have been justified. The opportunity presented itself of acquiring fully suitable premises at the Richmond Hill Hospital from the City Council, free of rent, and he had taken it up.

MR. COLONEL SPENDER-CLAY, on February 16th, asked what steps in the continuity of treatment, both for in- and out-patients, removal would involve, and if the consulting orthopaedic surgeon had agreed that the patients would not suffer. Mr. Macpherson replied that the transfer was entirely dictated by the need for public economy. The rent demanded for the building at Shepherd's Bush was £14,000, without security of tenure. The question of removal, therefore, did not resolve itself purely into a financial one. The medical staff would naturally prefer to remain in a building associated with so unique a standard of surgical efficiency. But he had no doubt that the change would not be detrimental to the interests of the patients. It was not possible to state the exact number of patients that would have to be trans-

ferred when the removal took place at the end of next month. He understood that the estimate of the cost of removal and adaptation would not be likely to exceed one half-year's rent that would have to be paid at Shepherd's Bush. There was no lease of the Richmond Park Hospital, but the First Commissioner of Works had agreed to its retention for at least two years, rent free. The matter of assisting out-patients who live near the Shepherd's Bush hospital was being considered.

Malaria in Ex-Servicemen.—Major Tryon stated, in answer to Mr. Frederick Roberts, on February 14th, that the Minister of Pensions was aware that, in dealing with claims to pension for malaria, difficulty sometimes arose in establishing the existence of the disease owing to the fact that it was active at long intervals only and for very short periods. He was, however, considering what better arrangements, consistent with his powers under the pensions warrants, could be made to meet this difficulty.

Milk Impurities.—In reply to Mr. Doyle, on February 15th, the Minister of Health said that he had for some time, in consultation with leading experts, been considering what steps should be taken to improve the milk supply, but he could not yet say whether it would be possible to introduce legislation this session.

The Asylums Inquiry.—Captain Loseby and Mr. Mills addressed, on February 15th, further questions to Sir A. Mond in regard to the departmental inquiry into lunatic asylum administration. The Minister repeated that in his opinion the tribunal appointed to investigate the allegations made by Dr. Thomas was quite impartial, and that it was now for the latter or to withdraw them. In reference to

Workers' Union to be represented at the inquiry, Sir A. Mond said that his information was that they refused because they wanted to have a representative on the Committee. Considering that they were the people who were mainly attacked by Dr. Lomax, it obviously would not be proper to put them on the Committee.

Food and Milk for Mothers and Children.—Asked, on February 15th, by Lieut. Colonel Fownall what would be the policy of the Ministry of Health during the next financial year in regard to the supply of food and milk to expectant and nursing mothers and young children, Sir A. Mond said that the circular he issued last December was designed to reduce an expenditure which had been found to be excessive. The circular also embodied medical advice as to the value of supplying meals instead of milk, which information he had received from his medical advisers and from outside persons of great weight. He had now received replies from most of them, and these were generally to the effect that they

he supply of milk, in view of the difficulty of arranging for the general supply of meals. He therefore proposed to continue during the next financial year the arrangements at present in force for the supply of milk under proper safeguards against abuse, allowing local authorities to substitute meat for milk where they desired and were able to do so.

Diphtheria in London.—Sir A. Mond, on February 15th, accepted a statement by Mr. Gilbert that the increase in the number of cases of diphtheria in London recently was abnormal. He regretted that it was impossible, in answer to a parliamentary question, to deal in detail with the preventive measures taken by the Ministry and the local authorities concerned, but he had reason to believe that they were satisfactory, and that a very large percentage of the total number of cases of diphtheria had been removed for isolation and treatment to the hospitals of the Metropolitan Asylums Board.

Mental Deficiency.—Mr. Leslie Scott asked, on February 16th, whether the Minister of Health had been able, in consultation with the Board of Control and the Treasury, to reconsider the position created by the circular of the Board of Control of August last in relation to the financial limitation of local authorities in dealing with urgent cases of mental deficiency. He asked whether the circular would not be withdrawn, as its operation would prevent large numbers of cases being dealt with under the Act, with results to the rates and taxes that would be far more expensive. Sir A. Mond said that in view of the economy which it should be possible to secure on the mental deficiency service generally, he hoped that local authorities could now make such provision as was essential to enable new urgent cases to be dealt with, and he was causing the Board of Control to issue a circular accordingly.

Orderlies in Pensions Hospitals.—Mr. Locker Lampson recently asked a question arising out of the Geddes report; he wished to know how many orderlies were employed in Ministry hospitals, and whether there was one orderly for every six patients. Mr. Macpherson said there were 1,679 orderlies employed in Ministry hospitals and convalescent centres, and there were 13,644 in-patients, but less than 50 per cent. of the orderlies were employed on nursing duties or in the wards. The remainder of the orderlies so termed were merely employees engaged on general domestic duties—for example, as messengers, sanitary men, store-men, gate-men, dining-room orderlies, gardeners, and ambulance drivers—and in the out-patient department, where 17,851 patients were being treated. In reply to another question, Mr. Macpherson said he was considering the issue of a memorandum on the Geddes report.

End of the Rabies Outbreak.—Sir A. Boscawen, in answer to Sir John Butcher, on February 20th, stated that all remaining muzzling and movement restrictions imposed on account of rabies (namely, those in force in Hampshire and Wiltshire) were removed on February 6th, no case of rabies having occurred in those areas nor in any other part of Great Britain for eight months. The Ministry of Agriculture had now every reason to believe that rabies had been entirely eradicated after a visitation of three and a half years.

England and Wales.

THE WELSH COMMITTEE AND THE WELSH NATIONAL SCHOOL OF MEDICINE.

THE Welsh Committee of the British Medical Association, which met at Shrewsbury under the presidency of Dr. W. B. C. Treasure, J.P., of Cardiff, was attended by Mr. Gwilym Hughes, the Organizing Secretary of the Welsh National School of Medicine appeal for £100,000 for further endowment and equipment. During the proceedings the Chairman read letters from Lord Kenyon, the Pro-Chancellor of the University of Wales, asking for the influence of the Welsh Committee in pressing upon the medical profession in Wales the claims of the Medical School, and also from Professor Ewen J. Maclean, J.P., suggesting that the Divisions of the Association might, at the instance of the Welsh Committee, be asked to circularize their members asking for individual contributions to the fund, and for the influence of the members of the Association in making known to the people of Wales the requirements of the National School. In reply to Dr. Alfred Cox, the Medical Secretary of the British Medical Association, and other members, Mr. Gwilym Hughes gave further information as to the progress of the appeal. The Welsh Committee unanimously resolved:

That this Committee warmly approves of the appeal of the Welsh National School of Medicine, and is of the opinion that it deserves the cordial support of the medical profession in Wales, and that the letters of Lord Kenyon and Professor Ewen J. Maclean be sent to the Divisions and Branches in Wales, with a suggestion that the Division or Branch, or both, should accept the offer of Lord Kenyon to invite the committee of the appeal to send a representative to address a meeting of the profession.

THE UNIVERSITY COLLEGE OF SOUTH WALES AND MONMOUTHSHIRE.

At the last meeting of the Court of Governors of the University College of South Wales and Monmouthshire a resolution was adopted pointing out that any diminution in the Government grants would seriously impair the efficiency of the College. Reference was made to the proposal to reduce the Government grant made to the universities through the University Grants Committee, and to the suggested withdrawal or suspension of the Government promise to contribute (on the £ for £ basis) the equivalent of all now contributions towards approved university purposes. The proposal would affect both appeals—that of the National School of Medicine and the College generally.

At the same meeting the draft supplemental charter was approved. During the discussion it was pointed out that the relation of the School of Medicine to the College might be defined by stating that the school was a unit within a unit; the Faculty of Medicine had, in effect, become almost a senate, but the College Council retained financial control. An amendment was proposed providing that the departments of anatomy and physiology, now under the direction of the College Senate, should be added to the list of departments coming under the jurisdiction of the Faculty of Medicine. The amendment was resisted by the Principal and others, and was finally rejected. The statutes were then adopted.

INFLUENZA IN BIRMINGHAM.

Influenza assumed epidemic proportions in Birmingham during the early part of January. There are distinct signs, however, that the wave has reached its maximum height and is now falling. For the most part the disease has been of the benign type, affecting all ages, especially young adults and the middle-aged, the schools having suffered little. Intense headache and distressing cough have been amongst the most prominent symptoms, the latter being very persistent. Grave pulmonary complications and fatalities have not been so numerous as in some previous epidemics.

By courtesy of the medical officer of health, Dr. John Robertson, we are able to publish the following information. During normal winter months there are from 0 to 6 deaths every week, with influenza as a cause; 40 to 60 deaths weekly from respiratory diseases; and from 15 to 30 notified cases of influenzal or acute pneumonia. The recent figures are as follows:

Week ending—	Respiratory Disease Deaths.	Influenza Deaths.	Pneumonia Notifications
December 31st, 1921 ...	42	4	18
January 7th, 1922 ...	48	8	28
January 14th ...	70	25	41
January 21st ...	86	43	119
January 28th ...	91	54	167
February 4th ...	84	46	142

The comparative figures of deaths from influenza are: in 1918, twenty-two per 1,000; in 1919, nine per 1,000; and in 1922, three per 1,000. It will be seen that the epidemic, although very widespread and attacking large numbers, has not been responsible for many deaths.

CONTRIBUTIONS TO HOSPITALS BY EMPLOYERS.

At the annual general meeting of the Midland Railway Company at Derby, on February 16th, Mr. Charles Booth, chairman of the company, referred to the financial position of the hospitals, which he said was so critical as to threaten the breakdown of the whole voluntary system throughout the country and to throw the hospitals upon the already overburdened taxpayer and ratepayer, with the consequent blighting influence of Government control. The Midland Railway Company had always subscribed to hospitals in the large towns on its systems, and, with the sanction of the shareholders, the directors had occasionally made large grants to the Derby Infirmary. A scheme had recently been put before the Midland Railway Friendly Society, and unanimously approved by it, which involved a weekly contribution from all weekly-paid employees, supplemented by a contribution on the part of the company. The Board had approved the principle of the proposals embodied in this scheme, and subject to its being generally adopted by the staff, was prepared to recommend it to the shareholders. On the basis suggested the company's annual contribution, if the scheme were universally applied, would substantially exceed the present subscriptions, but the alternative would be a much greater sum in rates, and he was confident that the shareholders would approve of the policy of the Board in the matter.

In a leading article published recently in our columns (January 14th, 1922, p. 70) it was pointed out that few large employers of labour have ever contributed sums really proportionate to the possible demands of their employees upon the hospitals. The scheme which was placed recently by the King Edward Hospital Fund before the London hospitals recommended a weekly contribution from employees, which it was hoped would be made at the place of employment by taking the contribution from wages, employers contributing a portion of the weekly payments. The Midland Railway Company, it will be seen, has adopted this idea, and it may be hoped that its example will be followed by other large employers, and that the hospitals throughout the country will benefit accordingly.

THE UNIVERSITY OF LONDON.

In his second lecture on the University of London and its possibilities, delivered at University College on February 20th, the Provost (Sir Gregory Foster) devoted himself again to answering the critics of the decision to accept the Government offer of the site at Bloomsbury instead of purchasing the site at Holland Park. Among other arguments, he mentioned that within a two-mile radius of the Bloomsbury site there were seven medical schools, with more than 3,000 students, as well as university colleges and schools providing for 11,000 students in other subjects. Bloomsbury was already in fact the university centre of London. Although a residential university like Oxford or Cambridge was not possible for London, the residential halls, which at present provided places for 1,040 students, ought to be increased to accommodate 4,000. The greatest need was for residential halls for post-graduate and research students, 90 per cent. of whom came to work within the University. He looked forward also to a great extension of the external work of the University in the shape of public lectures and tutorial classes, for which purpose, again, a

entual site was very desirable. During the next twenty years he saw a university "empire" being consolidated in London, with "dominions," practically self-governing, in the shape of the larger colleges, and "dependencies" with smaller powers. One crying need of the University was a great Institute of Public Health. There was a small department in this subject at University College, but quite inadequate for London. The Faculty of Medicine might readily become the greatest part of the University of London were it not for the hampering effect of the examination tests and tradition, which from the purely examination point of view made it more convenient to the student to get up what he could from textbooks; at the same time a great deal of teaching and research was carried on. The President of the Board of Education (Mr. H. A. L. Fisher), who presided, said that the University of London was a species to itself, unlike any other university in the world, and particularly unlike Oxford and Cambridge. The site had now been finally settled, unless, indeed, the University handed it back to the Government, an action which would be appreciated by the Chancellor of the Exchequer. Although the site at present contained only 11 acres, it was part of a large estate controlled by the Bedford Trust, comprising 50 acres or more, which would, he believed, come into the market during the next fifty years. Therefore the University could expand at leisure and become a worthy place of learning for the students, who, he believed, would come in increasing numbers to London from overseas.

Scotland.

GLASGOW MEDICAL LUNCH CLUB.

At the weekly meeting of the Glasgow Medical Lunch Club, on February 16th, Dr. E. P. Cathcart, F.R.S., Professor of Chemical Physiology in Glasgow University, was present as the guest of honour, and after lunch gave a most stimulating and helpful address. He made a plea for a more profound and continued study of the normal and its variations in the individual, and welcomed the desire on the part of the practitioner for post-graduate study; but too much of it was, in his opinion, devoted to the study of special branches of disease or of cases of unusual disease. Young graduates set out on their medical life full of enthusiasm and with high ideals based on hospital experience. They soon found that hospital work had not given a true reflection of general practice, and that they had to readjust their earlier ideas. A large part of their work was concerned with trivial conditions, such as coughs and colds, pains and aches, and mild digestive disorders. The immediate result was a feeling of depression owing to the lack of scope provided for their "Oster-crammed" brains, and this was liable to lead them to become the subjects of convention and hypnotic words and phrases. There were fashions in medicine, as in dress; of great variety, and the latest of these was licensed pornography masquerading under the name of psycho-analysis, which was a good thing, but, like all good things, liable to deterioration. The general decline of the death rate, and the greater expectation of life at birth, as shown in vital statistics, were in themselves satisfactory as showing advances in the prevention and treatment of disease, but still much information was lacking regarding the trivial conditions which caused such a loss of time to industry. The National Insurance Act had brought out the fact that from sickness alone there was an annual loss of over 14,000,000 weeks, which was enormous if capitalized at, say, £2 a week. Much of this sickness was preventable and trivial, and made up the ordinary round of the general practitioner. A knowledge of these conditions could only be obtained from the family doctor, not from the consultant, nor from those connected with the more scientific or academic side of the profession. Members of the profession had been too busy studying disease, when they ought to have been devoting much time to the normal and its variations. Such basal data of trivial illness were necessary for further advance in medicine, as only on such a foundation could the new temple of real medicine be reared. In the past they had looked to pathology, which was merely the record of failure, but now they must turn to physiology, which was the science of the normal. His opinion was that if post-graduate work were directed more to fundamental principles than to treatment the practitioner would return to his daily round with greater zest.

LISTER WARD AT GLASGOW ROYAL INFIRMARY.

At the annual meeting of contributors to Glasgow Royal Infirmary, held on February 13th, the decision of the managers that it was not in the interests of the institution to retain the Lister Ward was approved by the meeting. The managers, however, expressed willingness to allow the Lister Memorial Committee to remove the materials of the ward for re-erection, and they agreed that objects of interest and relics relating to the life and period of Lord Lister should be properly displayed in the Infirmary. Mr. James Macfarlane, the chairman, said that while the members of the Infirmary approved the motives of the Lister Committee, they had to point out that they had no ground to spare. The Memorial Fund Subcommittee had asked them to reconsider the decision they had reached several years ago that no part of the old building should be retained. The managers took the proposals into serious consideration, they viewed the site again, and the whole situation was discussed. The result was that they reaffirmed their previous decision that it was not in the interests of the Infirmary that the Lister Ward should be retained. At the same time the managers desired it to be known that they would welcome any proposal for commemorating Lord Lister's connexion with the Infirmary. During the recent controversy in the press it has been alleged, on the one hand, that the managers of the Royal Infirmary had taken a narrow, short-sighted, and parochial view of a sacred trust, possessing potentialities both historical and financial to which they appeared to be blind. There is considerable agreement with the opinion of Lord Blythwood that the Lister Ward should be retained, and there is little doubt that this opinion will be shared by many people both in this country and throughout the world. The ward has already been a Mecca for pilgrimages of scientists from all quarters of the globe. On the other hand, Sir George T. Beaton has expressed the hope that the decision of the directors of the Infirmary not to retain the Lister Ward may be accepted by all interested in the matter, and that no efforts should be made to overturn it either by protest or by agitation amongst the subscribers to the Infirmary. He suggests, therefore, that the Ward might be re-erected on another site, and in connexion with a Lister Memorial Hall, where, by lectures and demonstrations, the good work which Lister initiated as a surgeon might be extended.

CHAIR OF BOTANY AT EDINBURGH.

Sir Isaac Bayley Balfour has intimated his resignation from the chair of botany in Edinburgh University, to take effect from April next. He was born in 1853, and was the son of John Hutton Balfour, who was professor of botany in Edinburgh University from 1845-79; he graduated M.B., C.M. at Edinburgh in 1877, and M.D. (thesis gold medal) in 1883. He was regius professor of botany in the University of Glasgow from 1879 to 1884, and for the succeeding four years Sherardian professor of botany at Oxford. He was appointed to his present chair in 1888, and at the same time became regius keeper of the Royal Botanic Garden, Edinburgh. He received the honour of knighthood in 1920.

Ireland.

THE HEALTH OF THE IRISH NATION.

DR. RICHARD HAYES, T.D., who represents Limerick City and East Limerick in the Irish Parliament, recently delivered a lecture on hygiene, which has been published by the Lecture Society in a pamphlet. Dr. Hayes is one of the nine members of the Irish medical profession who were returned for Irish constituencies in the last parliamentary election. He voted for the acceptance of the Treaty. Much in regard to health reform is expected in Ireland from the new Irish Government, and with such an advocate as Dr. Hayes a good deal should be accomplished. The following are some extracts from his lecture:

"During the past fifty years the death rate in England has been reduced by 35 per cent., in Scotland by 30 per cent., and in Ireland increased by 2 per cent."

"In the past Ireland has been so preoccupied with a struggle for mere existence that many vital national problems have been necessarily overlooked, but to-day the national conscience has quickened and awakened to a sense of the national value of things. No interest in the national economy is of more fundamental importance than the nation's health, and none has been more neglected in the past. There exists here an effort and anomalous Poor Law Medical Service, on which the majority of the Irish

people have to depend for medical treatment. Outside a few of the large cities there is a deplorable lack of hospital services. There is no provision for research, the basis of all really progressive medicine. No independent sanitary service, no school medical service, exist here. There is no national scheme in child or maternity welfare to cope with the enormous wastage of infant life. The housing conditions in the cities are appalling, and the great domain of preventive medicine lies unknown and unexplored. Remembering such things, and the pernicious and subtle methods employed to extinguish the race, one cannot but wonder at that marvellous vitality inherent in the Irish people, who could survive what long ago would have destroyed any other race. That the national health has deteriorated there is, of course, no doubt, and much of that joy of life of the older generation owes its disappearance to that deterioration. One fact alone—the emigration of the flower of the race during the last century—must have had profound effect on its physical and mental fitness. The work before us now, however, is to survey our present position and build up a strong and virile people from what remains here. It is a great work, because a nation to express itself in all its richness and fullness, to realize its complete destiny, to draw to the full on its latent stores of human energy, must be fundamentally healthy. For the success of all health schemes in such a work many things are essential. The establishment of an Irish State is, of course, a prime necessity. Equally important is the co-operation and sympathy of the masses in all such schemes—and this cannot be obtained unless they possess some knowledge of the laws and broad principles of public health, with a realization of their vital significance. An enlightened public opinion is one of the first essentials, and never was it more necessary than now. We are at the beginning of a fresh era, and in the new world coming into being a severe struggle has already begun between nations, and only those of the highest efficiency will stand the strain. In Ireland local administration has just passed into the hands of a new generation fired with high ideals and stimulated by a broad national vision. Notwithstanding their limited powers, a good deal relating to the health and welfare of the community will depend on their zeal and efficiency. Further and greater changes are imminent here, bringing with them big responsibilities on all classes, and it is our duty to be ready and prepared for the work that lies ahead—the building up of a new and greater Ireland. In that great undertaking every class and individual will have their own special work to do; but there is one domain in which every man, woman, and child in the nation can play a part, and that is in laying the foundations of a healthy race. We must all realize that the greatest wealth of a nation lies, not in its soil, its mines, its water power, or its factories, but in the health of its people. Whatever social class one is born into, every one of us is born with a great individual heritage, and if the potential value of that wonderful birthright of health does not fully materialize with us here in Ireland, the failure is due in no small way to ignorance or neglect of the great simple laws of hygiene. We must realize that we have a high responsibility in the preservation of the national health; that such work is not the work of doctors alone; that a healthy race is not built up by skilled sanitarians or scientific legislators, but by the enlightened masses of the people. Every effort must be made to cultivate here a 'healthy conscience.' If every individual unit in the nation observed hygienic laws in his own personal sphere there would be few sanitary problems to trouble us. While the advancement of the public health of a community can of course be assisted by the wider activities of its public bodies, really satisfactory progress can only come through individual action founded on knowledge. Unfortunately, in Ireland there exists no provision in the educational programme of the country to impart such knowledge to the boys and girls of the nation. The remedying of that defect is a crying need. Even in a free Irish State all health schemes will come to naught unless founded on the hygienic education of the people. The housing question, for example, requires urgent attention, but even if satisfactorily solved it may be that the existing evil conditions and results will reappear unless the people acquire hygienic habits and knowledge."

Correspondence.

THE ORTHOPAEDIC HOSPITAL OF THE MINISTRY OF PENSIONS: AN EXTRAVAGANT ECONOMY.

SIR,—On February 16th questions were asked in the House of Commons about the decision of the Ministry of Pensions to abandon the special surgical hospital at Shepherd's Bush and instead to put the in-patients in an old military hut hospital in Richmond Park, and to make provision for out-patients in some more central place in London. In his reply, Mr. Macpherson stated that "the sole reason for this removal is the urgent necessity for public economy," and further that he "had no doubt that the proposed transference of the staff and the equipment to Richmond will be in no way detrimental to the interests of the patients." I cannot share his confidence on this latter point, and am sure that my surgical colleagues at Shepherd's Bush will agree with me. The efficiency of the work done in this and other similar hospitals has from the first depended on the principle of continuity of treatment and concentration of effort. The system of working has been that when a patient is sent to

the hospital the surgeon who sees him carries out any operative treatment required, directs the after-treatment by the special departments by personally seeing the head of the department, explaining what he has done and why. When the patient is well enough to be treated as an out-patient this further treatment is carried out by the same personnel who have seen his progress from the beginning. Further, the visiting surgeons have frequent opportunities of consulting each other.

The effect on the moral of the patients of finding themselves treated according to a regularly defined plan has been emphasized too often to need repetition.

The type of case which is being treated is changing. During the war there were many recent fractures with extensive open wounds. Two years ago these were healing up, and we were dealing with ununited and malunited fractures with ankylosed and flail joints, and, of course, always with results of injuries of muscles and nerves.

To-day a large proportion of these more obvious defects have already been dealt with by bone graft or other operations. The patient may have been away for months, and is now being sent back because, though the fractured arm may now be firmly united and function has returned, there remains some particular movement which he requires in his particular work which he cannot perform, and asks for an operation. Each case becomes, therefore, a problem by itself.

Thus the surgical work is becoming more difficult and also, it may incidentally be said, more interesting. In order to make these men fit to earn their living it is more necessary than ever to have every means of treatment thoroughly co-ordinated. This is not a mere matter of material equipment; it depends also on co-ordinated work among the staff.

Under the new arrangement there must be a double equipment—one at Richmond and one at the out-patient centre. At present if Mr. A. has a particularly difficult case on which he wants to consult Mr. B., even if the latter is seeing out-patients, he is in the building, but under the new arrangement the surgeons will have to divide their time and energies between two institutions miles apart. X rays taken when the patient is first seen in the out-patient department will have to be sent out to Richmond when the patient, some weeks later, is admitted for treatment there, then back again when the man becomes an out-patient.

Inevitably there will be much dissipation of the surgeon's time and energy when working under these conditions. This means less effective results in some patients and in most delay in getting the results. This point should be carefully considered, for payments of allowances to men waiting for treatment may easily amount to a large sum when the number of patients dealt with amounts to several thousand every year. From inquiries made the financial difficulty between the Government and the Hammersmith Board of Guardians, in whose infirmary the hospital is housed, seems to have arisen as follows:

From 1916 to 1919 the hospital was military, and no rent was paid to the guardians. In 1919 the whole institution, with all the new additions built by the War Office with the generous assistance of the British Red Cross, was handed over to the Pensions Ministry. The guardians then asked for and received a rent of £8,000 a year. In 1921, finding that the outgoings to meet expenses on the buildings exceeded this by £1,300, the guardians wrote to the Ministry of Pensions suggesting that the rent should be increased to £10,000. Several months passed without any definite reply being given, so someone suggested that they might get a reply if they were to give the Pensions Ministry notice to quit unless it paid £14,000 a year. The Minister of Pensions offered £12,000, which was refused.

It is difficult to believe that a deadlock like this can be allowed to interfere with the welfare of wounded soldiers. The ratepayers and guardians of Hammersmith were offered £12,000, which was more than they had themselves asked for a few months earlier, therefore they probably would not lose anything by accepting this sum; and it is not pleasant to think that they would wish to make a financial profit at the expense of the wounded men, even though they may have grounds for being annoyed with the delays of a Government office. On the other hand, the Ministry has a duty to the Treasury, and must resist what seems to it unfair financial pressure. It is sincerely to be hoped that a way may be found for reopening negotiations and maintaining a great institution in its fullest vigour.—I am, etc.,

London, W., Feb. 23/22.

D. McCRAE AITKEN.

A DIPLOMA IN TUBERCULOSIS.

SIR,—I venture to forward you a copy of the regulations or the Tuberculous Diseases Diploma (Wales),¹ which has just the sanction of the University authorities, and the first examination for which will be held at Cardiff, I hope, on the first Tuesday and Wednesday of July next.

The reasons that are thought to render such a diploma are as follows:

The number of Government appointments for whole-time tuberculosis work is now very large, and likely to increase in the future. In order to find suitable recruits for these appointments it is necessary that young medical men should have an opportunity of taking up special courses in the study of this disease and presenting themselves for an examination, the successful passing of which will provide them with a diploma as evidence that they have devoted a period of real study to the disease which they are about to deal with.

The extreme importance of pulmonary tuberculosis has undoubtedly tended to concentrate attention upon this form of the disease. The institution of a standard examination, study for which must necessarily involve the examination of the disease as a whole, including its surgical characters, must raise the standard of knowledge and improve the methods of dealing with tuberculous patients; while it is undoubtedly true that our preventive measures are likely to be based on sounder lines if greater account is given to tuberculosis as a general rather than a local disease.

It is hoped to ensure to the T.D.D. (Wales) examination the high standard that alone can make a diploma worth having, and to this end it is proposed to invite external examiners of recognized position as authorities on medical and surgical tuberculosis to assist in conducting the examinations.

It is realized that at the present moment difficulties may arise for would-be candidates in obtaining the courses of instruction which are laid down in the regulations for admission. These difficulties appear inevitable under the circumstances, and can only be solved when universities, medical schools, and tuberculosis hospitals are prepared to initiate the classes of instruction which are necessary for candidates belonging to Category B. The imperative necessity for these definite courses in the case of young medical men without whole-time experience of the disease will be generally recognized. Arrangements are being made to give these special courses to medical graduates in the Welsh National School of Medicine at Cardiff, and particulars can be obtained on application to the Professor of Tuberculosis or to the Registrar.—I am, etc.,

S. LYLE COMINS,

Professor of Tuberculosis, University College
of South Wales and Monmouthshire.

Cardiff, Feb. 16th.

THE TREATMENT OF EMPYEMA.

SIR,—I have read with interest both the annotation in the *BRITISH MEDICAL JOURNAL* of February 11th, entitled "A physician on the surgical treatment of empyema," and Dr. J. A. Nixon's paper on "Progress in the treatment of empyema" which is there reviewed. To quote Dr. Nixon's words:

"Routine resection and drainage undoubtedly save many lives, and not infrequently good functional recovery takes place in the affected lung. But we cannot be ignorant of the numerous instances in which the patient recovers with a sadly impaired lung, with a lung that remains hopelessly contracted, or even with a sinus in the chest wall which obstinately refuses to close."

Two methods are mentioned as improvements on the orthodox treatment by drainage of the pleural cavity after excision of a portion of a rib. These are (a) aspiration, which, if necessary, is repeated, and (b) thoracotomy by a long incision through an intercostal space, without excision of rib, but of sufficient size to permit of free access to the pleural cavity; through this incision the hand is introduced, all lymph and fibrin are removed, and the chest wall is completely closed at the conclusion of the operation. That the unfortunate results mentioned by Dr. Nixon are not infrequently met with is certainly true; and my object is to bring forward certain points in the after-treatment of the usual operation, which I have found of the greatest value, rather than to criticize these suggested alternative methods of treatment.

I should, however, like to point out that aspiration has been extensively tried, and though "it has long been known that pneumococcal empyemas sometimes clear up after aspiration

alone," yet this fortunate result occurs in only a small proportion of cases, and on this account has not found general favour with physicians. Aspiration is commonly employed in the more serious cases to give relief and as a preliminary to excision of the rib and drainage of the pleural cavity. I can also recall operating on two cases which had been treated by repeated aspiration, which had failed to have a satisfactory result, and had set up a troublesome complication—cellulitis of the chest wall, which required several additional incisions.

Though I have on several occasions made an incision through an intercostal space as a preliminary or palliative measure in cases of pneumococcal empyema where the condition of the patient has been very grave, I have no experience of the other method of treatment suggested by Dr. Nixon. The operation strikes one as considerably more severe than the usual procedure, especially in a patient who is gravely ill, and one questions the desirability of interfering with layers of exudate which may have a protective function.

For some twelve years or so I have used Bier's treatment by suction cups as a routine method after resection of rib and drainage for empyemas, the great majority of which have been pneumococcal. The operation is performed in the usual way and a large rubber tube is inserted. On the second or third day this is removed, cleaned, and shortened, so that it projects but a short distance into the thoracic cavity. A large-sized Bier's cup is then fitted over the wound, with the drainage tube about the centre, and suction is applied by compressing the rubber bulb. The suction is kept up for about five minutes, and, after a few minutes' interval for the oedema to subside, may be repeated for a similar period. The cup is then removed, the wound and the tube again cleaned, and a dressing applied. This treatment is repeated twice a day. Usually the discharge rapidly diminishes, the temperature comes down, and the general condition of the patient improves. As the wound contracts the large tube is replaced by a smaller one. The treatment is continued as long as there is any discharge, and until the superficial wound has closed to such an extent as to render drainage unnecessary. There may be some bleeding from the superficial granulations, but this is not important, and can be obviated by diminishing the amount of suction. One minor advantage is that the patient is usually interested in the treatment.

There are several important practical points to bear in mind. The cup must be of sufficient size—for an adult at least three and a half inches in diameter. It must fit accurately and easily to the chest wall; this may be a real difficulty, for these cups are usually made for application to a flat surface. It is, however, possible to get them shaped so as to fit readily to the curve of the chest.

The usual rules in all applications of Bier's treatment must be observed—namely, that no pain must be caused, and that the suction must not be too great or continued for too long a time. From five to ten minutes twice a day will suffice. The drainage tube should always be in position while the treatment is being carried out, except possibly in the later stages where the wound is merely a sinus, as otherwise the suction may have a valvular action, drawing the edges of the superficial wound together, and preventing any action on the pleural cavity. The cup, of course, must be carefully cleaned after use, and before it is applied to the wound it should be sterilized by standing in some antiseptic solution.

The suction cup acts in three ways:

1. It sucks out any discharge which may remain in the pleural cavity.
2. It must produce some passive hyperaemia of the pleura, and so exert the antibacterial action which it is generally agreed is the result of the passive hyperaemia produced by Bier's treatment.
3. As the result of the diminished pressure in the pleural cavity it must have some effect in promoting expansion of the lung.

One is occasionally asked by a physician to see a case of empyema that has been operated upon, and that after some weeks is not doing well, with a view to providing freer drainage. These cases usually do remarkably well with Bier's treatment. As an example I will mention a case that I have recently been asked to see by my colleague, Dr. Fawcett.

A boy, aged 8 years, was operated upon for empyema on January 9th, 1922. The temperature promptly dropped to normal and remained so for a week; it then rose again, and from January 16th to February 3rd showed a typical septic chart with a morning temperature of about 99° and an evening swing to between 102° and 103°. When I saw him on February 3rd there was a sinus from which a little pus was oozing, and no discharge appeared to escape through it the drainage tube had been omitted. I suggested

¹ The regulations are printed at p. 333.

STREPTOCOCCAL INFECTION BY THE NASAL
AND BUCCAL PATHS.*

BY

DANIEL C. EDINGTON, M.D.,

PENRITH.

It is interesting to trace the recognition of the nasal and buccal areas as points of incidence of infection. From 1885 to 1890, in the early days of bacteriology, many varieties of unclassified and unnamed bacteria were demonstrated in sections of decayed teeth and by needle culture from teeth cavities. Later came Hunter, with his researches on pernicious anaemia, which he attributed to absorption from infection, septic teeth, or septic mucous membranes connected with teeth, producing a subacute or chronic systemic bacterial infection. Later it was accepted that frequently after an attack of acute tonsillitis there followed in about fourteen days a more or less subacute rheumatism. This pointed to the tonsillar pharyngeal mucous membrane as an area of infective incidence. Then came the recognition of pyorrhoea with its strepto-bacillus and its importance as a possible cause of many diseases, prominently rheumatic diseases. We know of cases of acute streptococcal poisoning from Ludwigian angina types, also from septic tonsillar abscesses, sometimes associated with infectious diseases, frequently not; also of cases of septicaemia following tonsillar or tubal manipulations. We have accessory sinus suppurations due to streptococcal infection, and cases of rheumatic fever sometimes following excision or enucleation of the tonsils too soon after rheumatic tonsillitis. Again, in association with influenza epidemics, at odd times and places we meet with cases of streptococcal pneumonia, primary and secondary, with a high mortality; and, most important of all, a definite recognition and classification has been given within the last few years to the infective endocardial conditions.

The question I wish first to discuss is the path of infection of these various systemic conditions and the prominent part played by the nose, nasopharynx and throat, and the lymphatics and veins associated with these organs.

Paths of Infective Distribution from Nasal, Nasopharyngeal and Buccal Membranes.

Lorrain Smith has strongly emphasized the question of the incidence and distribution of any and all infections; what determines the selective distribution of organisms to any particular organ or organs? We do not know why streptococci from the mouth or nose should select the fibrous thickened cardiac valve-cusps for attack, as in subacute infective endocarditis, or why tuberculous infection in some cases should select the suprarenal glands, ignoring the nearer and larger organs. Rosenow and others in America have, recently demonstrated the possibility of duodenal and gastric ulcers, appendicitis and colitis, being due to streptococcal infection from the mouth and teeth. Many of these diseases are possibly merely local craters in a general blood infection.

Venous and Lymphatic Drainage.

The mouth venous drainage is mainly by the pterygoid plexus and facial veins to the internal jugular vein and so into the circulation, and from the tongue directly by lingual veins into the internal jugular vein. There are also connexions with the pharyngeal venous plexus. The teeth venous drainage passes from the inferior and superior alveolar veins into the pterygoid plexus and facial veins and thence to the internal jugular vein. The mouth lymphatics drain to the submaxillary, submental and parotid lymph glands, whose efferents pass to cervical lymph glands. The tongue lymph glands drain from the sides and middle of the dorsum to glands at the carotid bifurcation. The teeth lymph drains to the submaxillary, submental and parotid lymph glands.

The nasal venous drainage is mainly to the pterygoid plexus from the spheno-palatine in the spheno-palatine foramen, also importantly connected with ethmoidal tributaries of the superior ophthalmic veins and tributaries of the angular vein at the bridge of the nose. Infection might pass this way into the orbit or to venous sinuses as the ophthalmic veins enter the cavernous sinus and the angular veins are connected with the anterior end of the superior sagittal sinus. The nasal external lymph vessels pass to parotid and submaxillary lymph glands, and some few to the superficial

cervical lymph glands. The muco-periosteum anteriorly drains externally to the submaxillary glands and posteriorly to the superior deep cervical glands and the lateral retropharyngeal glands. The nasopharyngeal venous drainage is mainly spheno-palatine, etc., into the pharyngeal plexus and thence to the internal jugular vein. The nasal lymphatic drainage is to superior deep cervical lymph glands, and some to the retropharyngeal lymph glands—hence arise retropharyngeal abscesses.

The palatine tonsil lymph vessels pierce the pharyngeal wall laterally and end in glands on the internal jugular vein below the posterior belly of the digastric at the level of the angle of the jaw. The venous connexion of these regions with the meninges is brought about by the drainage into the venous pterygoid plexus, which receives (1) emissary veins through the foramen ovale from the cavernous sinus, and (2) connexions from the inferior ophthalmic vein through the inferior orbital fissure. A circle is thus formed by the pterygoid plexus, nasal veins and other connexions, with ophthalmic veins and the superior longitudinal sinus, the ophthalmic veins entering the cavernous sinus and emissary veins passing to the pterygoid plexus.

Bacteriology of the Nasal, Nasopharyngeal and Buccal Mucous Membranes.

Broadly speaking, the nasal healthy secretion is non-bacterial. The sinuses if healthy are sterile, the vestibule is usually bacterial and sometimes pathogenic, containing varieties of staphylococci and micrococci and streptococci. In 26 cases of healthy mucous membrane, Lewis and Turner found streptococci in 6, staphylococci in 13, and pneumococci in 4. In an unhealthy nose and nasopharynx the three prominent bacteria are streptococci, staphylococci and pneumococci in varying strains, together with at times the influenza bacillus and certain putrefactions and coryzal bacilli, etc. All nasal inflammations are due to pathogenic organisms, either virulent, or capable, if avirulent, of being stimulated to virulence by chills, traumatism or debility; hence the onset of acute sinus abscesses after coryzal colds and sore nose conditions in extreme asthenia during pulmonary tuberculosis, typhoid fever, etc.

The nasopharyngeal and mouth varieties of organisms are much the same as the nasal, and are derived from food, water, and air. Teeth show organisms on the surface of dentine, and also in the deeper tissues. Mouth acids are always a result of bacterial action; they decalcify teeth, and so start caries; thus in deep dental caries we find streptococcal varieties along with the *Bacillus necrodentalis*, etc. There are many varieties of bacteria in the mouth—fermentative, pathogenic, etc. Accessory sinuses are sterile if healthy. If unhealthy, they usually show streptococci, staphylococci, and pneumococci, with catarrhal bacteria, and sometimes the *Bacillus coli communis*; in other words, the same varieties of bacteria as are found in the buccal and nasal cavities. In a hundred cases investigated (Lewis and Turner) 75 per cent. showed streptococci, 74 per cent. showed pneumococci, and 70 per cent. staphylococci, with occasional *Bacillus diphtheriae* and *Bacillus influenzae*, etc. These details are from the research works of Lewis and Turner, Reynolds, Fraser, Ritchie, etc.

Antral suppurations are 58 per cent. nasal in origin, 30 per cent. of these beginning by influenza attacks; 14 per cent. only are coryzal in origin, 37 per cent. are due to infection from teeth; and 2 per cent. are traumatic (Lewis and Turner). Streptococci are more numerous in chronic than in acute sinus suppurations, in the proportion of 80 per cent. to 60 per cent. Thus from nasal, nasopharyngeal and buccal cavities the above pyogenic organisms, together with Pfeiffer's bacillus, pneumococci, meningococci, and tubercle bacilli, are capable of passing to the brain, probably by venous channels, and producing such diseases as suppurative, influenzal, pneumococcal, and epidemic cerebro-spinal meningitis, also probably acute poliomyelitis and tuberculous meningitis, tuberculous and septic cervical glands; and, by way of the Eustachian tube, middle-ear disease and mastoid infection; while in the general system by absorption through the lymphatic channels of mouth and nose and nasopharynx, pneumonia, pernicious and septic anaemias, infective endocardial conditions, rheumatoid arthritis, etc., may be established. The main paths of infection are the lymphatic channels, but probably venous to the meninges. Broadly speaking, the same infective chief organisms—namely, the streptococci, staphylococci and pneumococci—are found in the nasal, pharyngeal and mouth mucous membranes, and by way of the Eustachian tube the

* Presidential address, Border Counties Branch, British Medical Association, September 23rd, 1921.

A DIPLOMA IN TUBERCULOSIS.

SIR,—I venture to forward you a copy of the regulations for the Tuberculous Diseases Diploma (Wales), which has just received the sanction of the University authorities, and the first examination for which will be held at Cardiff, I hope, on the first Tuesday and Wednesday of July next.

The reasons that are thought to render such a diploma desirable are as follows:

The number of Government appointments for whole-time tuberculosis work is now very large, and likely to increase in the future. In order to find suitable recruits for these appointments it is necessary that young medical men should have an opportunity of taking up special courses in the study of this disease and presenting themselves for an examination, the successful passing of which will provide them with a diploma as evidence that they have devoted a period of real study to the disease which they are about to deal with.

The extreme importance of pulmonary tuberculosis has undoubtedly tended to concentrate attention upon this form of the disease. The institution of a standard examination, study for which must necessarily involve the examination of the disease as a whole, including its surgical characters, must raise the standard of knowledge and improve the methods of dealing with tuberculous patients; while it is undoubtedly true that our preventive measures are likely to be based on sounder lines if greater account is given to tuberculosis as a general rather than a local disease.

It is hoped to ensure to the T.D.D. (Wales) examination the high standard that alone can make a diploma worth having, and to this end it is proposed to invite external examiners of recognized position as authorities on medical and surgical tuberculosis to assist in conducting the examinations.

It is realized that at the present moment difficulties may arise for would-be candidates in obtaining the courses of instruction which are laid down in the regulations for admission. These difficulties appear inevitable under the circumstances, and can only be solved when universities, medical schools, and tuberculosis hospitals are prepared to initiate the classes of instruction which are necessary for candidates belonging to Category B. The imperative necessity for these definite courses in the case of young medical men without whole-time experience of the disease will be generally recognized. Arrangements are being made to give these special courses to medical graduates in the Welsh National School of Medicine at Cardiff, and particulars can be obtained on application to the Professor of Tuberculosis or to the Registrar.—I am, etc.

S. LYLE CUMMINS,

Professor of Tuberculosis, University College
of South Wales and Monmouthshire.

Cardiff, Feb. 16/22.

THE TREATMENT OF EMPYEMA.

SIR,—I have read with interest both the annotation in the BRITISH MEDICAL JOURNAL of February 11th, entitled "A physician on the surgical treatment of empyema," and J. A. Nixon's paper on "Progress in the treatment of empyema," which is there reviewed. To quote Dr. Nixon's words:

"Routine resection and drainage undoubtedly save many lives, but not infrequently good functional recovery takes place in the unoperated lung. But we cannot be ignorant of the numerous instances in which the patient recovers with a sadly impaired lung, with a lung that remains hopelessly contracted, or even with a sinus in the chest wall which obstinately refuses to close."

Two methods are mentioned as improvements on the orthodox treatment by drainage of the pleural cavity after excision of a portion of a rib. These are (a) aspiration, which, if necessary, is repeated, and (b) thoracotomy by a long incision through an intercostal space, without excision of rib, of sufficient size to permit of free access to the pleural cavity; through this incision the hand is introduced, all pus and fibrin are removed, and the chest wall is carefully closed at the conclusion of the operation. That the unfortunate results mentioned by Dr. Nixon are not infrequently met with is certainly true; and my object is to bring to certain points in the after-treatment of the usual cases, which I have found of the greatest value, rather than to criticize these suggested alternative methods of treatment.

I should, however, like to point out that aspiration has been fully tried, and though "it has long been known that pneumococcal empyemas sometimes clear up after aspiration

alone," yet this fortunate result occurs in only a small proportion of cases, and on this account has not found general favour with physicians. Aspiration is commonly employed in the more serious cases to give relief and as a preliminary to excision of the rib and drainage of the pleural cavity. I can also recall operating on two cases which had been treated by repeated aspiration, which had failed to have a satisfactory result, and had set up a troublesome complication—cellulitis of the chest wall, which required several additional incisions.

Though I have on several occasions made an incision through an intercostal space as a preliminary or palliative measure in cases of pneumococcal empyema where the condition of the patient has been very grave, I have no experience of the other method of treatment suggested by Dr. Nixon. The operation strikes one as considerably more severe than the usual procedure, especially in a patient who is gravely ill, and one questions the desirability of interfering with layers of exudate which may have a protective function.

For some twelve years or so I have used Bier's treatment by suction cups as a routine method after resection of rib and drainage for empyemas, the great majority of which have been pneumococcal. The operation is performed in the usual way and a large rubber tube is inserted. On the second or third day this is removed, cleaned, and shortened, so that it projects but a short distance into the thoracic cavity. A large-sized Bier's cup is then fitted over the wound, with the drainage tube about the centre, and suction is applied by compressing the rubber bulb. The suction is kept up for about five minutes, and, after a few minutes' interval for the oedema to subside, may be repeated for a similar period. The cup is then removed, the wound and the tube again cleaned, and a dressing applied. This treatment is repeated twice a day. Usually the discharge rapidly diminishes, the temperature comes down, and the general condition of the patient improves. As the wound contracts the large tube is replaced by a smaller one. The treatment is continued as long as there is any discharge, and until the superficial wound has closed to such an extent as to render drainage unnecessary. There may be some bleeding from the superficial granulations, but this is not important, and can be obviated by diminishing the amount of suction. One minor advantage is that the patient is usually interested in the treatment.

There are several important practical points to bear in mind. The cup must be of sufficient size—for an adult at least three and a half inches in diameter. It must fit accurately and easily to the chest wall; this may be a real difficulty, for these cups are usually made for application to a flat surface. It is, however, possible to get them shaped so as to fit readily to the curve of the chest.

The usual rules in all applications of Bier's treatment must be observed—namely, that no pain must be caused, and that the suction must not be too great or continued for too long a time. From five to ten minutes twice a day will suffice. The drainage tube should always be in position while the treatment is being carried out, except possibly in the later stages where the wound is merely a sinus, as otherwise the suction may have a valvular action, drawing the edges of the superficial wound together, and preventing any action on the pleural cavity. The cup, of course, must be carefully cleaned after use, and before it is applied to the wound it should be sterilized by standing in some antiseptic solution.

The suction cup acts in three ways:

1. It sucks out any discharge which may remain in the pleural cavity.
2. It must produce some passive hyperaemia of the pleura, and so exert the antibacterial action which it is generally agreed is the result of the passive hyperaemia produced by Bier's treatment.
3. As the result of the diminished pressure in the pleural cavity it must have some effect in promoting expansion of the lung.

One is occasionally asked by a physician to see a case of empyema that has been operated upon, and that after some weeks is not doing well, with a view to providing freer drainage. These cases usually do remarkably well with Bier's treatment. As an example I will mention a case that I have recently been asked to see by my colleague, Dr. Fawcett.

A boy, aged 8 years, was operated upon for empyema on January 9th, 1922. The temperature promptly dropped to normal and remained so for a week; it then rose again, and from January 16th remained so for a week; it then rose again, and from January 16th to February 3rd showed a typical septic chart with a morning temperature of about 99° and an evening swing to between 102° and 103°. When I saw him on February 3rd there was a sinus from which a little pus was oozing, and as no discharge appeared to escape through it the drainage tube had been omitted. I suggested

that the sinus should be dilated with dressing forceps, a small drainage tube inserted, and Bier's treatment started twice daily. The temperature came down at once. On February 4th the evening temperature was only 99.4°, and since then it has never risen above 99°. The discharge has nearly ceased, the wound looks quite healthy, and the general condition of the boy has greatly improved.

The object of treatment should be, to quote Dr. Nixon's words, "the ultimate restoration of function as well as the immediate saving of life." I believe the line of treatment described above to afford the simplest and surest means of attaining these ends.—I am, etc.,

London, W., Feb. 14th.

PHILIP TURNER.

MALARIAL GLYCOSURIA.

SIR,—In your issue of February 4th there appears a letter from Dr. Orlebar, in which he states that an instance of glycosuria published by us in the *BRITISH MEDICAL JOURNAL* for August 26th, 1921, as of malarial origin, was in fact a case of glycosuria due to hyperthyroidism. After carefully considering our notes, of which only a brief abstract was given in our paper, we are still of our original opinion, for the following reasons:

1. The pulse was 120 on admission only, when the temperature was 99.8° and the man was getting over an acute attack of malaria. The next day the temperature was 99° and the pulse 80, and on this day the urine showed 8.5 grams of glucose per litre.

2. The glycosuria persisted in spite of absolute rest in bed, and also in spite of 30 grains of quinine a day by the mouth for a long period; it only disappeared completely after this treatment was intensified by a course of intramuscular injections of quinine. It is our experience that all manifestations of malignant tertian malaria respond much more satisfactorily to quinine administered in this form than to quinine by the mouth.

3. The man was examined by a medical board at Brighton in August—two months after leaving Orpington. They found "no active signs of malaria," but much more definite signs of hyperthyroidism, including exophthalmos. In spite of this his urine then contained no sugar.

Dr. Orlebar gives also two reasons against the glycosuria being of malarial origin:

1. That the man had had much quinine before coming to Orpington.

2. That he continued to have much malaria after leaving Orpington.

Both these reasons appear to us to be unsound. In the first place, Sir Ronald Ross has pointed out the prime necessity of regular administration of quinine in the treatment of malaria. A note made at the Brighton clinic in March states: "Taking quinine, Meyer's test negative." It is apparent, therefore, that as long as the man was an out-patient, the regularity of his quinine treatment could not be guaranteed.

In the second place, apart from the findings of the Board in August, a further note from the Brighton clinic states that the man was admitted to Endsleigh Gardens Hospital in October and very shortly afterwards discharged as showing "no evidence of malaria."

To sum up: the man had definite glycosuria, which persisted until he had had a thorough course of quinine treatment under supervision. It then disappeared, as also did the signs of malaria, if the findings of the Brighton Board and Endsleigh Gardens Hospital are correct.—We are, etc.,

CANCER RESEARCH.

SIR,—Considerable publicity has been given recently to the work of the Imperial Cancer Research Fund, the Middlesex Hospital, and many other institutions, in the columns of the daily press.

Among the many other deserving institutions engaged in this research, not mentioned, it may be well to remind your readers of the work which is being done in the physiological and bacteriological laboratories of King's College, which has been carried out for many years by Dr. J. A. Shaw-Mackenzie, and without any financial assistance.

The generous offer of Lord Atholstoun and of Sir William Veno towards cancer research work raises the question of the medical side in cancer treatment, and encourages this aspect of the problem. That this aspect of the problem is justified may be gathered from the facts that cancerous tumours in the human subject may remain stationary over considerable periods of time, and that disappearance of cancerous growths

occurs spontaneously in a large percentage of inoculated tumour mice. These facts seem to indicate that defensive processes of the body are at work.

In this connexion one of the results of the laboratory investigations is that the blood serum of recovered mice shows that natural chemical processes are at work, and that a natural and increased production of lipase and of fatty acids in the tissues are important factors in the protective mechanism. The same reactions of the serum held good in recovered tuberculosis and other bacterial diseases examined. It has been shown, further, that sodium oleate, amongst other substances, increases the action of lipase *in vitro* and *in vivo*, and beneficial results have long been reported from its use in certain cases of inoperable cancer.

It is accordingly not unreasonable to hope that it is in the direction of reinforcement of natural processes that advances in treatment may be made. It was on this basis that (1) preparations of saponified extracts derived from the fatty material and lipoids of cancerous and tuberculous material have been made, and the same suggested from other pathological tissues. Further investigations are being continued on the (2) trial and therapeutic efficacy of these preparations; (3) examination of serums, including complement fixation tests in cancer; (4) the composition of cancerous material, with special reference to the fats and fatty acids.

It is interesting to note that the work of C. C. Warden at the University of Michigan and St. Josephs of Mercy Hospital, Ann Arbor, which is reviewed in the February number of *Medical Science*, issued by the Medical Research Council, London, appears to be on similar lines. While, however, in this work "the specific antigens of cells, bacterial and somatic," are attributed to suitably dispersed fatty acids, the importance in particular of the bacterial fatty acids and their sodium salts is evident in immune processes.—I am, etc.,

King's College, Feb. 18th.

W. J. SMURSON.

THE PREVENTION OF VENEREAL DISEASE.

SIR,—I ask for space for a short comment on Lord Gorell's letter in your issue of February 18th in which he refers to me as knowing well the efforts he has made in the direction of demanding a public inquiry conducted by men of independent standing on the one essential point which divides the two societies, and, in fact, was the sole reason of the establishment of the Society for Prevention of Venereal Disease.

In three private interviews which took place in January, 1921, between Lord Gorell and myself, I was strongly impressed by his evident desire to have this important matter thrashed out in all its aspects independently of Government or other officials. I had become convinced of the necessity of such an inquiry for some few years. Lord Gorell and I were agreed that no conference between the two societies alone could be fruitful. For the one point at serious issue between them was an indivisible one as regards the S.P.V.D.

Since the occasion of these interviews I know of no further efforts by Lord Gorell in the above-mentioned direction. But the following facts do not indicate that the National Council for Combating Venereal Diseases or its president are trying to assist in any measure towards the composing of the present difficulties, which are doubtless deplorable.

1. In February, 1921, a special committee of the Birth Rate Commission, at which both the societies were represented, issued a report that practically supported the main arguments of the S.P.V.D. Soon afterwards the Bishop of Birmingham invited the two societies to a round-table conference with him, which the S.P.V.D. accepted on condition that the general findings of this report should be accepted. This condition led to the refusal of the N.C.C.V.D. to attend the conference, which consequently was not held.

2. In June, 1921, the British Humane Society, consisting largely of many important public men, invited the N.C.C.V.D. and the S.P.V.D. to send representatives to a conference on this matter. The S.P.V.D. accepted the invitation without making any condition. The N.C.C.V.D. declined it.—I am, etc.,

Feb. 20th.

H. BRYAN DONKIN.

PREVENTION OF VENEREAL DISEASES IN THE AUSTRALIAN IMPERIAL FORCE.

SIR,—Sir Archdall Reid has asked me to state what I know of the facts regarding the "compulsory issue of disinfectants, accompanied by both printed and verbal instructions in their use, to all men proceeding on leave" in the Australian Imperial Force. My experience is that these regulations were

more honoured in the breach than in the observance. As in Paris from April, 1918, to May, 1919, and I do not believe that 10 per cent. of the Australians arriving in Paris have had disinfectants issued to them. I met practically every train for several months, and I know of my own knowledge that the men were without prophylactic outfits. I communicated with the D.M.S. and each A.D.M.S. in the Australian Divisions, and once or twice succeeded in getting a small parcel of fifty outfits, but usually these medical officers could send me none, because they were out of supplies myself. I bought supplies myself in Paris, and for some these received payment later from the A.I.F.; they paid altogether about £120 on Paris chemists' receipts. The Australians and other British troops were supposed to be able to get tubes from the Pénitence Barracks (British Medical Report Centre), but sometimes for a week or ten days or longer the barracks had no tubes at all. In any case one tube at a time was issued from there, and men proceeding on leave to Rome, Nice, etc., were actually sent away these areas, where there were no ablution rooms in existence, with one single-treatment calomel tube in their pockets. This was the army system. I tried to see every man proceeding on leave to Nice or Rome, and give him a prophylactic kit containing at least ten calomel tubes, ten 2-grain tablets of potassium permanganate, and a small syringe and some cotton-wool. During 1919 most A.I.F. men who could afford time to Paris several times on leave officially or unofficially, my thousands of men were absent without leave at different times, and of course prophylactic outfits were not issued to men before they left camp, and they stood clear of Paris headquarters to avoid arrest. In England the same conditions prevailed. In May, June, and July I was lecturing Salisbury Plain in different Australian and New Zealand camps. The officers in command were usually under the effect that outfits were being issued to men going on leave, that this covered the matter. It did not—because so many men went away for week-ends without permission, and there was frequently shortage of supplies. I always held the matter thus on the lecture platform: Hands up, men who have been on leave, officially or unofficially, without prophylactic outfits. As a rule from 80 to 90 per cent. of the audiences promptly held up their hands. As to issue of disinfectants being "compulsory," my opinion was that men should carry a prophylactic outfit as a "field-dressing" in the same way as they carried a "field-kit," but actually the Anzacs always had the option of it. I have no doubt that the Australian medical officers felt their best to instruct the men and provide them with disinfectants from 1914 to 1919. But there was a war on at the time!—I am, etc.,

London, W., Feb. 20th.

ETHEL A. ROY.

HENRY OF NAVARRE.

Sir,—Some short time back Sir Charles Ballance in his *Mass Vicary Lecture*, speaking of multiple trephining, stated that the classic instance was that of Henry of Navarre, whose surgeon trephined him twenty-seven times. The statement has passed without challenge; but was Henry IV ever trephined? I have seen no allusion to it in temporary history, and it is not mentioned in the memoirs of the Duc de Sully, which are practically an autobiography of Henry IV from his early manhood to his death.—I am, etc.,

London, N.W., Feb. 18th.

H. A. CLOWES.

GERMAN-MADE X-RAY APPARATUS.

Sir,—A brief study of the contributions which have recently appeared in your pages discloses the unpleasant fact that the medical profession are already patronizing German manufacturers by purchasing x-ray and electro-medical apparatus of German origin, in particular equipments for therapy treatment.

Equally good, if not superior, apparatus is manufactured in this country, there is no excuse for purchasing these from our late enemies.

There are nearly 2,000,000 unemployed in this country, it is therefore everyone's duty to assist in stimulating industries rather than those of Germany; we wonder whether those who place their orders abroad appreciate the terrible result of their action.

Adequate support is not forthcoming for the British manufacturer, he obviously cannot continue, and will

gradually cease to construct British x-ray and electro-medical apparatus, and seek the easier and possibly more remunerative path of representing a foreign house and so satisfying the demands of the English medical profession.—I am, etc.,

February 14th. A MANUFACTURER OF BRITISH APPARATUS.

AN IMPROVED METHOD OF DEMONSTRATING LANTERN SLIDES.

Sir—Use of the lantern for lecture purposes in the common fashion offers several inconveniences. First, the room must be darkened, a condition that hinders note-taking, prevents demonstration of specimens, and favours somnolence; secondly, the windows must be closed, a great disadvantage in warm weather; thirdly, a lantern attendant is necessary, and the number of slides to be shown may be few or many; fourthly, arc illumination is required. In order to overcome these and other objections, I devised, and since October last have had in constant use, the following modification.

The lantern is provided with a gas-filled incandescent lamp (1,500 c.p., 7.5 amp.) and, instead of the usual method whereby an assistant projects the image on the wall behind the lecturer—that is, some 15 feet from the front row of students—in the method under description the lecturer himself operates the lantern from his bench, controlling the light by an ordinary tumbler switch. The image is projected upon and viewed through a ground-glass screen placed 3 feet from the front row of students. Hence the usual method, in which the projection lens points towards the lecturer and a large dead-white receiving screen is situated behind him, is replaced by a method in which the projection lens points towards the audience, and a small translucent screen intervenes between lecturer and audience.

As a result of its nearness to the observer the image need not be so large for proper vision, and a ground-glass screen of which each side measures 26 in. is sufficient. But the principal point is that, owing to the sufficiency of a smaller image and its nearness to the observer, the law of inverse squares governing illumination operates at so great an advantage that the image on the screen is clearly visible in diffused daylight or ordinary artificial illumination of the lecture theatre even in the back rows, 20 ft. from the ground-glass screen.

For a lamp using 7.5 ampères special wiring is necessary, but Messrs. Fallowfield, Charing Cross Road, are supplying a complete outfit, consisting of lantern, lamp (800 c.p.) resistance, screen, and stand (cost £15), that can be worked from the ordinary lighting circuit by means of an adapter.

One proviso is necessary: It is impossible for the apparatus to compete with direct sunlight. The blinds must be drawn on that side of the room into which the sun's rays enter. If this be done, an observer at a distance of 30 to 40 feet from the screen can see the image well, even at noon on the brightest day in October. Whether he will be able to do so in June I do not yet know. I believe the modification will be of great practical use to teachers.—I am, etc.,

W. S. LAZARUS-BARLOW.

Cancer Research Laboratories,
Middlesex Hospital, W., Feb. 17th.

A CONFUSION OF NAMES.

Sir,—I shall be greatly obliged if you will allow me the opportunity of stating in your columns that I neither have nor ever have had any kind of connexion whatever with the commercial preparation known as "dimol," or any other "antiseptic" of commerce.

It is not possible for me to find the leisure to reply personally to the communications and inquiries which continue to reach me from time to time (owing to an inconvenient accidental similarity between my name and another) regarding the merits or demerits of advertised antiseptics. But it seems to me undesirable to appear, by silence, to admit either the accuracy and propriety or the relevancy to myself of opinions addressed to me by correspondents under a misapprehension.—I am, etc.,

University College, Oxford, Feb. 16th. E. W. AINLEY WALKER.

MORE persons were sent to asylums for the insane in New York State in 1921 than in any previous year, according to the *Journal of the American Medical Association*. At the end of 1921 there were 39,735 patients in the thirteen hospitals for the insane in the State, 1,445 more than there were a year previously, and 6,642 more than the nominal capacity of the hospitals.

Obituary.

DR. BERTRAM HAROLD KINGSFORD died on January 29th, at Sherwood, Woking, from acute leukaemia of under three weeks' duration, at the age of 51. Bertram Kingsford was born in Chelsea and educated at Merchant Taylors School, London, and received his medical training at St. Thomas's Hospital. He became M.R.C.S., L.R.C.P. in 1892, M.B.Lond. in 1895, and M.D.Lond. in 1905. After leaving St. Thomas's he held various resident posts in London and other hospitals, having been house-physician and house-surgeon at the West London Hospital. For two seasons he was surgeon on the Nile steamers. He went to Woking twenty-five years ago. In the course of a busy professional life he was always ready to give the benefit of his medical knowledge for the furtherance of any good work. He had been actively engaged with the Woking Division of the British Red Cross Society, instructing many in first aid and nursing for many years. He was one of the honorary medical officers of the Victoria Cottage Hospital. For some years he had held the appointment of police surgeon to the Woking Petty Sessional Division, public vaccinator of the Woking District under the Guildford Union, and certifying factory surgeon to the district. Dr. Kingsford was a prominent Freemason, being a member and past-master of the Weyside Lodge and a member of the Chesselden Lodge; he was also an old member of the British Medical Association. A colleague writes: Kingsford built up a large practice in Woking, by reason of his untiring efforts, great sympathy and kindness; knowing the end that awaited him, his fortitude, bravery and unselfishness were an example to all. He will be missed sadly by his devoted patients, friends and colleagues. The memorial service, which was most impressive, was attended by hundreds, representative of various interests, to pay a last tribute to the memory of their friend. His remains were cremated and buried at Brookwood Cemetery, beside the ashes of his wife, who died three years ago. Kingsford leaves one daughter to mourn his loss.

WE regret to announce the death, on February 13th, of Mr. CHARLES WRAY, of London and Croydon. He received his medical education at the London Hospital, and took the diploma of M.R.C.S. in 1881, proceeding to the F.R.C.S. in 1886. He specialized in ophthalmology, and was ophthalmic surgeon to the Croydon General Hospital and to the infirmary and council schools at Croydon. He was a member of the Ophthalmological Society and of the British Medical Association. Dr. E. H. Willock, late honorary secretary, Croydon Division, writes: By the death of Charles Wray the British Medical Association has lost a staunch supporter. He was a most active member of the Croydon Division and Surrey Branch, and no clinical meeting was ever complete without an exhibition of interesting cases by him. As an ophthalmologist he was frequently in advance of the times. He was a skilful and careful operator. On vast experience, his opinion was much sought after and valued for the soundness of its judgement. Wray was a great and original thinker on many subjects. He was generous, almost to a fault. His left hand never knew what his right hand did, and everything was bestowed without publicity or ostentation. Many of his professional brethren have lost a good friend in Charles Wray.

DR. AUGUSTINE MARSHALL of Lowestoft died on February 2nd. Born in Leeds in 1866, he was educated at St. Thomas's and the London Hospitals. He took the diploma of M.R.C.S., L.R.C.P., and L.S.A. in 1894, the M.D.Brux. in the same year, and the D.P.H. in 1899. For some twenty years he had been medical officer of health for the borough and port of Lowestoft, and was also school medical officer. He was always mindful of the welfare of the town as a health resort and brought about many hygienic improvements. Dr. Marshall had not been in good health lately, but continued to attend to his official duties and to the large number of cases recently at the sanatorium, where he was taken ill suddenly. He was formerly honorary assistant surgeon to the Lowestoft Hospital, held many public appointments, and was a member of the North Suffolk Division of the British Medical Association. A keen yachtsman, a hard-working and painstaking official, in private practice considerate and comforting, his loss will be greatly felt in Lowestoft.

THE death is announced of Dr. GEORGE SAMUEL WILD of Farnfield and Bootle. He was educated at Liverpool, where he became Derby scholar in clinical medicine and surgery in

1884, in which year he took the diplomas of M.R.C.S.Eng. and L.R.C.P.Edin. In 1892 he took the D.P.H.R.C.P.S.I., and graduated M.D.Durh. in 1900. He was consulting physician to the Bootle Borough Hospital, and showed great interest in public affairs. He served as a town councillor for a long term, and was appointed Mayor of Bootle in 1901. He was created an alderman in 1903, but retired in 1908. In November, 1903, he was appointed a Justice of the Peace, and continued to act on the rota ever since. He was a member of the Southport Division of the British Medical Association. Dr. Wild is survived by his widow and a daughter.

DR. THOMAS FRANKLIN PEDLEY died suddenly of heart failure at Bridge House, Rangoon, on January 13th, aged 67. He was the eldest son of the late George Pedley of The Haven, Surrey, and was educated at Guy's Hospital, taking the diplomas of M.R.C.S. and L.S.A. in 1876, and the M.D. of Brussels in 1879. Shortly after he went out to Burma, and had practised in Rangoon for over forty years, holding for many years the post of health officer of the Port of Rangoon, and latterly that of honorary medical officer of the Dufferin Maternity Hospital. He joined the Rangoon Port Defence Volunteers as medical officer in 1880, rose to the rank of surgeon lieutenant-colonel, and received the Volunteer Officers Decoration in April, 1899. He also held the first class gold medal of the Kaiser-i-Hind Order.

DR. JOHN GORDON LESLIE, late temporary Captain R.A.M.C., died at Guildford on January 23rd, aged 57, of septicaemia, caused by a scratch from a needle while performing a *post-mortem* examination. He was educated at Edinburgh, where he graduated M.B. and C.M. in 1893, and before the war was in practice at Newent, Gloucestershire. He joined the R.A.M.C. as a temporary lieutenant on August 1st, 1917, became captain after a year's service, and during the war served in Egypt. He was on board the *Braemar Castle* when she was torpedoed in the Mediterranean.

LIEUT.-COLONEL GEORGE HERBERT LE MOTTE, R.A.M.C. (ret.), died in Guernsey on January 18th, in his seventy-second year. He was educated at Elizabeth College, Guernsey, and Marlborough, and at King's College Hospital; he took the diplomas of M.R.C.S. and L.S.A. in 1872, and became M.D. of St. Andrews in 1884. He entered the Army Medical Service in 1875, passing into it at the head of the examination list. His military service was spent chiefly on foreign stations—South Africa and India. His last appointment was in India, as head of the Military Hospital in Quetta, an appointment he held for four years. He returned home on sick leave in 1901, and shortly afterwards retired. In 1902 he returned to his native island, and in the same year was elected a Jurat of the Royal Court. During almost twenty years of public service he held the office of Supervisor and Treasurer of the States for two years, and was also President of the St. Peter Port Harbour Committee and of the Board of Health. In the latter capacity he was instrumental in effecting many improvements and innovations, often in the face of great difficulties. He had a very large circle of friends, and his old-fashioned courtesy possessed a peculiar charm of its own. Colonel Le Motte married in 1889, and his widow and two daughters survive him.

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE.

AT a congregation held on February 17th the following were among the degrees conferred:

M.B. AND B.CH.—E. L. Dobson, L. P. Costobadie, K. J. Yeo.
M.B.—J. M. Lawrie.

UNIVERSITY OF BRISTOL.

THE following candidates have been approved at the examinations indicated:

FINAL M.B., CH.B.—P. Phillips, M. Critchley, W. K. A. Richards.
Part II (Completing Examination): Phyllis Beames, Madge E. Golding, W. A. Jackman, Winifred G. Nott, Victoria S. Tryon.
Part I (including Forensic Medicine and Toxicology): B. A. Crook, J. M. Evans, Constance L. Griffiths, F. J. Hector, Marguerite G. Hughes, Frances M. Jones, A. J. Kceville, E. C. K. Kenderdine, Doris M. Pullen, J. A. L. Roberts, H. L. Shepherd. Part I only: F. H. Bodman, Carrie H. Osmond, H. J. H. Spencebury.
* With first class honours. † With second class honours.

CH.M.—(Gynaecology): R. S. S. Statham. (Laryngology): E. Watson-Williams.

THE WELSH NATIONAL SCHOOL OF MEDICINE. THE TUBERCULOUS DISEASES DIPLOMA, UNIVERSITY OF WALES (T.D.D. WALES).

Regulations: Curriculum and Certificates.

CANDIDATES for the Tuberculous Diseases Diploma (T.D.D.) must possess a medical qualification registrable for practice in Great Britain and Ireland, be not less than 25 years of age, and either, (a) have held a post-graduate diploma for a period of not less than five years, for work on tuberculosis, and presented (i) A certificate of general suitability for work in connexion with tuberculosis, signed by a tuberculosis physician, medical superintendent, medical officer of health or other medical man under whom or with whom the candidate has worked for at least one year. (b) Certificates in support of the fact that the candidate has worked for five years in whole-time tuberculosis appointments, signed by the representatives of the authorities for whom the work was performed, or by the administrative medical officer concerned; or, Category B, have held a registrable qualification to practise for at least one year, and presented the following certificates: (the courses may be taken concurrently) (a) A certificate of satisfactory pursuance of a course of consecutive post-graduate study of the clinical and medical school, or months' duration at hospital where such certificate of satisfactory pursuance of post-graduate practical study of the pathology and bacteriology of tuberculosis of three months' duration at a tuberculosis laboratory or a recognized general laboratory where such a course is given. (c) A certificate of three months' satisfactory attendance at a tuberculosis institute or dispensary. (d) A certificate of general suitability for work in connexion with tuberculosis, signed by a professor of tuberculosis, or the Dean of the Medical Faculty, or the registrar of the hospital where the course of six months' duration covered by certificate (a) has been satisfactorily pursued.

Examination.

The diploma will be granted to such candidates as pass an examination divided into two parts, as follows:

Part 1.—(a) A written examination on the clinical and epidemiological problems of tuberculosis. (b) Including the examination of patient, physical signs found to be present, the specimens, and a *vis-à-vis* examination.

Part 2.—A written and practical examination on the pathology of tuberculosis. But in the case of candidates who have been remitted on the submission and acceptance of the results of clinical or epidemiological investigation carried out by the candidate in connexion with tuberculosis, or of reprints or copies of not less than two original articles on tuberculosis published by the candidate in the medical press.

Part 1 will be held annually on the first of July in each year. Notice of candidature fee of £10 10s. and the necessary certificates, must be forwarded to the Registrar of the University, University Registry, Cathays Park, Cardiff, not later than June 15th.

Medical News.

It is understood that Sir Alfred Mond has made substantial progress in negotiations with various authorities and interests with the object of getting agreement for a Pure Milk Bill. His hope is to introduce and pass a measure this session, but that may depend on the propinquity or otherwise of a general election. The probability is that the lines for legislation would be the establishment of a standard for milk, and the grant of greater powers to local authorities for inspection of dairies. An important point not yet decided is whether the exercise of such powers should be compulsory or optional. The establishment of a standard would not necessarily debar the sale of lower grade milk.

At a meeting at Essex Hall, on February 21st, the University of London Labour Party adopted as its parliamentary candidate Dr. W. H. R. Rivers, F.R.S., Praelector in Natural Science, St. John's College, Cambridge. Mr. Sidney Webb, the candidate at the last election, who is standing for another constituency, proposed the adoption of Dr. Rivers, and among those who spoke in his support was Sir Arthur Newsholme, who described Dr. Rivers as the most advanced and original anthropologist in this country, whom the University would honour itself by electing. The proposal was unanimously approved; and Dr. Rivers, in accepting the invitation to stand, mentioned that he was himself a London graduate, and that his whole academic career until he was 30 years of age had been passed in London University. He expressed his whole-hearted adherence to the Labour programme, which as a scientist newly turned to politics he found very satisfying on account of its clear-cut principles. He criticized the Geddes proposals so far as they related to education. The meeting was small, but several persons of distinction sent messages. Sir Sydney Russell-Wells is the Conservative candidate.

The special six weeks' course in surgery, arranged by the Fellowship of Medicine and Post-Graduate Medical Association, began on Monday last, and will be continued during the next five weeks. There is a morning and afternoon session on each day, and the appointments have been so arranged as to involve a minimum of travelling. Full particulars can be obtained from the Secretary of the Fellowship of Medicine, 1, Wimpole Street, W.1.

At a meeting of the medical staffs of voluntary hospitals in Birmingham, held on February 13th, Mr. Albert Lucas and Mr. William Billington were elected representatives of the Birmingham Voluntary Hospitals Committee appointed to assist the Commission charged with the distribution of the Government grant of £500,000 for the benefit of voluntary hospitals, and for the co-ordination of services and appeals.

Mr. JOSEPH BARCROFT, F.R.S., Fellow of King's College, Cambridge, delivered the sixth Harvey Society Lecture at the New York Academy of Medicine, on February 11th, on "The *raison d'être* of the red corpuscle."

The programme for the ensuing session of the Child Study Society, London, includes a lecture by Mr. Macleod Yearsley, F.R.C.S., entitled "A plea for the deaf child," on April 6th, and a paper on April 27th on "The natural defences of the upper air passages," by Dr. Octavia Lewin. The meetings are held on Thursdays, at 6 p.m., at the Royal Sanitary Institute, Buckingham Palace Road, S.W.1; particulars can be obtained from the secretary, Miss H. M. Richards, at that address.

A GRANT of 75,000 dollars has been made to the Health Commissioner of New York to employ additional medical practitioners, nurses, and inspectors in connexion with an unusual number of scarlet fever cases in the city, and to take precautions against the possible recurrence of an epidemic of infantile paralysis, which usually runs in cycles of five or six years. In 1920 there were 6,885 cases of scarlet fever in New York, in 1921 there were 13,880. Part of the grant will be spent on the laboratory study of scarlet fever and infantile paralysis.

PROFESSOR CHAUFFARD has been elected vice-president of the Académie de Médecine for 1922.

The lecture committee of the Boston (U.S.A.) Society of Natural History has reorganized itself into the Committee for the Protection of Animal Experimentation, and an appeal for funds signed by leading men of science in America has brought, it is stated, an encouraging response. The committee was formed to combat the activities of the various antivivisection societies in America, which were beginning to menace the health of the community; in California last year, for instance, a measure that threatened all animal experimentation was defeated with some difficulty.

DR. HENRI CLAUDE has recently been appointed professor of mental diseases in the Paris Faculty of Medicine in succession to the late Dr. Ernest Dnpré.

The University of Toronto has instituted a post-graduate course for a diploma in radiology. Candidates for the diploma are required to be graduates in medicine of a university recognized by the Senate, and must also have spent at least one year after graduation in a resident appointment at a recognized hospital. The curriculum for the diploma extends over eight months, and includes radiographic technique and interpretation, and gastro-intestinal examination.

A COURSE of five lectures dealing with recent researches on the accessory food factors will be given by Dr. S. S. Zilva at the Battersea Polytechnic, Battersea Park Road, S.W.11, on Thursdays, from 5.45 to 6.45 p.m., commencing on March 2nd. The fee for the course is 10s.

DR. G. O. C. MACKNESS of Broughty Ferry has, on the occasion of his retirement from practice, been presented by his friends and patients with a cheque for £700 as a mark of their esteem for his services to the community.

AMONGST the volumes announced for early publication by Messrs. J. and A. Churchill is *The Principles of Radiology*, by Dr. J. A. Crowther, University Lecturer at Cambridge in Physics Applied to Medical Radiology; it will contain fifty-five illustrations, and deals with the physical side of the subject. Messrs. Heinemann will shortly publish a book on anaesthetics in practice and theory, by Dr. Joseph Blomfield, O.B.E.

DURING the week ending February 18th the number of deaths from influenza showed a further decrease. In the 105 great towns the figures were 670 against 759 in the previous week. In London there were 17 fewer deaths from the disease than in the week ending February 11th (22 against 103). There was an increase in Liverpool (54 against 43). In Cardiff, Edinburgh, and Glasgow the number of deaths from influenza were 19, 24, and 23 respectively, against 27 in the first-named town and 43 in the latter two in the previous week. While in the aggregate of the 105 great towns there was an increase of 403 deaths from all causes, the deaths from influenza showed a decline of 83.

THE British Committee for Aiding Men of Letters and Science in Russia has received a letter from Professor Oldenburgh, Permanent Secretary of the Academy of Sciences, at Petrograd, stating that the books dispatched in ten cases from this country had been received and had been placed in a special reading room at the House of Savants. He expresses the deep gratitude of scientific workers in Petrograd for this stimulating intellectual aid. The British Committee considers that its work is now at an end. It received altogether £448. Out of the surplus it has spent £50 on books for the University of Latvia, and the small balance will be handed over to the Universities Committee of the Imperial War Relief Fund.

THE use of solutions of hypochlorites for the disinfection of water and to assist in the disinfection of clothes in the laundry is well known. Messrs. Vincent Roberts and Co., engineers of Leeds, have a machine which produces sodium hypochlorite by electrolysis and can be used wherever an electric current is available. They have issued a leaflet containing some reports from factories and institutions where their electrolyser has been used with success. In a note appended by the firm to these reports there is an error. "Disinfectants," it is stated, "only disguise unpleasant smells." The distinction is between disinfectants, antiseptics, and deodorizers. An effective disinfectant used in proper proportions destroys the organisms with which it is brought into contact, and this is what the hypochlorites do. Antiseptics inhibit bacterial growth and prevent decomposition. Deodorants merely oxidize or absorb malodorous products. Reference may be made on this point to *Hygiene and Public Health*, by Parkes and Kenwood (sixth edition).

It is reported that the number of foreign medical students in France increased from 1,192 in 1920 to 1,555 in 1921.

THE idea of making all sizes of medicine bottles with the same size of neck (to fit an ordinary 6 oz. bottle cork) should prove exceedingly useful to the dispensing practitioner; such bottles are being made by the Medical Requisites Company, of 54, Deansgate, Manchester.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

IN order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, Aitiology, Westrand, London; telephone, 2630, Gerrard.

2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate, Westrand, London; telephone, 2630, Gerrard.

3. MEDICAL SECRETARY, Medisecra, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

QUERIES AND ANSWERS.

TREATMENT OF TAENIASIS.

A CORRESPONDENT writes that a patient of his has been afflicted with a tapeworm (*Taenia saginata*) for the past six years, which has defied all attempts to remove it. Filix mas, pomegranate, and pelletierine have all been tried; only the first gives any satisfactory result, but the head has never been found. Our correspondent invites suggestions as to further treatment.

Some years ago Sir James Kingston Fowler described in our columns (April 14th, 1906, p. 841) a method of treatment which he had employed for some time with success. (1) The patient is kept in bed. (2) For two or three, or in some cases four, days the diet consists of: Beef-tea, 2 pints; Mason's essence, one tin; two rusks; and port wine 4 ounces. During the same period the patient takes tinctoids of cascara sagrada (gr. ij) three times daily. (3) On the fourth day (usually) at 5 a.m. *haustus sennae* co. 5j; at 9 a.m. a capsule containing *mv* of the extract of male fern; at 9.15 ditto; at 9.30 ditto; at 9.45 ditto; at 11 a.m.

haustus sennae co. 3j. If by 1 p.m. the worm has not been passed and the head found a second course of treatment with male fern at intervals of fifteen minutes is begun; to be followed in an hour by a purgative draught. If the head is not found a third course of treatment is prescribed. It is rarely advisable to continue the treatment beyond this without an interval of a day, as the patient may be somewhat exhausted.

INCOME TAX.

"K. R." asks how he should show the ownership of his residence by his wife on his income-tax form.

** In making a declaration of total income the assessed value should be shown as income of the wife, and any payments from which tax is deductible should be detailed in the space provided on such declarations.

LETTERS, NOTES, ETC.

DR. EDGAR CYRIAX asks us to correct an error made by him in his letter published in the JOURNAL of February 11th, p. 247: Line 11-12 should read "which had been diagnosed as influenza," instead of "which had been diagnosed as scarlet fever."

THE TREATMENT OF PNEUMONIA WITH CREASOTE.

"M.D." writes: The treatment of pneumonia with a mixture containing 5 minims of creasote and 10 grains of potassium iodide in each dose, to be given every four hours, the dose of creasote to be increased if necessary, has been advocated on several occasions in the BRITISH MEDICAL JOURNAL. As the use of creasote may have fallen into disrepute, I would suggest that the large dose of potassium iodide—a drachm daily—may be a defect in the mixture, for in such large doses it probably acts only as a depressant. Given in doses of 2 to 3 grains it has a well marked expectorant action, and the addition of a stimulating expectorant such as aromatic spirit of ammonia, is advantageous. The prescription will then run as follows: *Creasote mv; pot. iod. gr. ij; sp. ammon. aromat.; sp. rectificat., ext. glycyrrhizae liquid., aa ʒss; aq. chloroformi ad ʒj*; to be given every four hours. Probably not more than two ounces of brandy will be necessary in the twenty-four hours. The potassium iodide should be omitted in cases with profuse expectoration. I believe it is sometimes beneficial to remove the pillows and raise the foot of the bed, if the patient can bear it, by way of draining the bronchi and aiding the expulsion of the sputum.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

DR. RICHARD GILLBARD (Willesden Green) writes: The control of the Royal College of Surgeons by the Fellows has been discussed week after week in the lay press—a Sunday newspaper. I hazard a guess, therefore, it will not be debarred from a medical one. Apart from the suggestive comparison of the M.R.C.S. and F.R.C.S. with the B.A. and M.A. of Oxford and Cambridge Universities, the fact remains the F.R.C.S. men are a mere fraction of the College. It is a question of democratic control and the Members being masters in their own house—of the House of Lords being over the Commons, the peers above Pym, Pili, and Balfour. If the Members with these basic facts affronting them acquiesce in the status quo and government by the Fellows, it is not possible to afford sympathy. They deserve what they "are about to receive."

BIRTH CONTROL AND ABORTION.

DR. MARIE C. STORES writes: As President of the Society for Constructive Birth Control and Racial Progress, may I register our committee's regret that in your otherwise excellent paragraph on abortion in Austria you have unfortunately headed it "Birth Control in Austria"? True, the words are in inverted commas, but we think it most deplorable that abortion should ever be referred to under the misnomer "Birth Control."

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 26, 27, 30, 31, 32, and 33 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 28 and 29.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	0 9 0
Each additional line	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 15 0
Half page	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *posteo restante* letters addressed either in initials or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

174. The Etiology and Treatment of Rickets.

JUNDELL (*Hyggea*, November 30th, 1921) is sceptical as to the soundness of the modern teaching that rickets is simply the response to a lack of vitamins in the food. He adduces many arguments in favour of his hypothesis that the disease is the result of faulty formation of endogenous ferments (hormones), the result of overloading the nutritive functions of certain of the endocrine glands by an ill-chosen and too generous diet. Working on this hypothesis, he has treated his cases of rickets on a system which he calls "relative inanition." By this process of partial starvation he claims to have achieved excellent results, and if the disease has not progressed too far, semi-starvation alone is enough to effect a rapid cure. And when relative inanition is supplemented by a phosphorus fish oil régime, even the worst forms of rickets can be cured in one to two months. But fish oil alone (he refers presumably to cod-liver oil and the like) cannot prevent the outbreak of rickets if the child continues to be overfed. The author's system of relative inanition consists of cutting down the total calorie supply to 65 to 70 calories per day per kilogram body weight (the normal being 100 calories per kilogram body weight). This means giving about 60 to 75 c.c.m. of milk per kilogram body weight daily, and small quantities of sugar, cereals, and fresh vegetables and fruit. And, according to the age of the child, other foods can be given, such as eggs, fish, and meat. The child's weight is stationary or diminishes under this treatment, which does no harm because it is not continued for long, and which is justified not only by its rapid effect on rickets, but also on such allied conditions as laryngo-spasm and other manifestations of spasmophilia.

175. Quinidine in Cardiac Therapy.

WYBAW (*Le Scalpel*, January 14th, 1922) says quinidine must not be looked upon as a cardiac tonic. Its chief action is to re-establish normal rhythm in cases of arrhythmia in auricular fibrillation. In auricular flutter and extra-systoles it is of little or no use. Hence the great importance of diagnosing the exact nature of the cardiac irregularity. The absence of presystolic murmur is constant in fibrillation. Digitalis may be given at the outset, and then quinidine in adequate doses, 1.25 to 1.50 grams per diem. When the heart is regular it is advisable to give digitalis in small doses for four days, then quinidine for five days, and after two days' rest start the cycle again. In some patients quinidine upsets the stomach, and when this is the case it is better not to persevere. Symptoms of quinine poisoning may also occur (tingling in the ears, cyanosis, erythema, etc.). In the author's experience quinidine is contraindicated in advanced cases; in old sclerotic patients, and in some old-standing cases who have become accustomed to the cardiac irregularity, it is better to leave things as they are. In some cases, though the fibrillation is cured by quinidine, the pulse remains quick. Probably quinidine acts by prolonging the duration of the refractory period during which a muscle fibre remains insensible to a fresh stimulus. The heart can be regulated in about 50 per cent. of the cases, but it is difficult to present to say beforehand what case will respond.

176. Treatment of Syphilis with Salvarsan Alone.

REFTING (*Tidsskrift for Den Norske Lægeforening*, January 13th, 1922) reviews his experiences of salvarsan during the last ten years. He has given 10,200 injections of old salvarsan, 2,100 of neo-salvarsan, and 200 of silver salvarsan, and has never seen alarming symptoms. He thinks that most of the salvarsan fatalities can be traced to over-dosage of faulty technique; possibly also to salvarsan which has deteriorated, and to its simultaneous exhibition with mercury. He has seen 19 cases of reinfection, all of which satisfy the strict stringent standard set for the diagnosis of reinfection. He classifies the 1,749 cases of syphilis which he has treated with salvarsan alone under ambulatory conditions according to the disease was primary, secondary, tertiary, or latent. In primary cases are also classified according to Wassermann's reaction was positive or negative before treatment; according to the dosage of salvarsan. All his 169 cases of primary syphilis with a negative Wassermann before institution of treatment (which consisted of at least five injections) remained symptom-free, and the Wassermann reaction continued to be negative. The author concludes that in this class of case five intravenous injections

(0.50 to 0.60 gram for men, and 0.30 to 0.40 gram for women) at fortnightly intervals are sufficient to cure the disease. For serum-positive cases in the first stage the first five injections at fortnightly intervals should be followed by more (number not stated) injections at three or four weeks intervals. In secondary and tertiary syphilis also the author finds that salvarsan alone is usually adequate.

177.

Luminal in Epilepsy.

JACKSON and FREE (*Therap. Gazette*, December 15th, 1921) studied the continued use of luminal in twelve individual cases of epilepsy, with a view to ascertain its effects upon those cases with post-epileptic furor and confusional states, and upon the seizures, as well as the results from long usage and following its withdrawal. They confirm existing opinion as to its power of reducing the number of seizures, the dosage, and the absence of untoward effects from its use; but in five of the cases treatment was continued over a further period of nine months. By charting the number of seizures before and during administration, and after its withdrawal, it was seen that luminal in 14 grain daily doses reduces the convulsion curve, but that after a time the effect is lost, and there is a secondary elevation of the curve. This can be again lowered if the dose is increased, to be followed later by another secondary rise. Complete withdrawal is followed by a distinct elevation, which in two of the cases resulted in severe seizures, status epilepticus, and death. While reducing the number of convulsions the drug does not effect a cure, its prolonged use is dangerous and its withdrawal requires great care. In two of the cases the degree of post-epileptic furor and confusion was lessened. While giving temporary relief its routine use is questionable, because the establishment of tolerance necessitates bigger dosage, and because of the dangers of its continued use and withdrawal.

178.

Displacements of the Trachea.

ARMAND-DELILLE, HILLEMAND, LESTOCQUOY, and MALLET (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, December 23rd, 1921) discuss the displacements of the trachea in chronic pulmonary tuberculosis; they found marked deviation in 10 out of 300 cases, nearly as frequently to the left as to the right. The condition resembles a pulmonary cavity, but betrays itself by digital palpation and retraction of the corresponding half of the thorax, with displacement of the apex beat. Radioscopic examination shows a shadow up to the level of the seventh cervical vertebra, which passes obliquely to the right or left, and reaches the sterno-clavicular articulation, bordering on the apex of the lung; or a marked vertebral shadow, covering the first and second dorsal vertebrae, and describing a curve at the apical summit, adjoining the sterno-clavicular articulation, and returning to the median line; or, again, the trachea is displaced *en masse*, and may follow a line parallel with the border of the sternum. LAUBRY and BLOCH (*Ibid.*) describe the same condition in which the oesophagus was also displaced, but to a less extent, with the trachea, and the four authors first quoted corroborate this condition, which may be the cause of the dysphagia of which patients sometimes complain.

179.

Marking Ink Poisoning.

BORINSKI (*Deut. med. Woch.*, December 15th, 1921) observes that marking inks belong to two main classes. In the one a black colour is obtained by the reduction of certain metals such as silver; in the other the colouring matter is some organic substance, usually aniline black. With the increased cost of metals since the war the aniline marking inks have grown in popularity. But they are dangerous unless the directions given for their use are conscientiously followed, and the chlorhydrate of aniline is converted into the stable, non-toxic aniline black by washing garments in cold soapy water and a little soda before use. The author reports two small epidemics of aniline poisoning in hospitals where infants' nappies were used without preliminary washing, with the result that several of the infants collapsed suddenly with cyanosis and other signs of acute poisoning. In one case the urine was found to contain p-aminophenol—a decomposition product of aniline. The author refers to two other recent reports on poisoning by marking ink (*Deut. med. Woch.*, No. 39, and *Muench. med. Woch.*, No. 13), the writers of these accounts making out that the poisoning was due to nitrobenzol. The author could not find this substance in either of the two kinds of marking ink he examined; both kinds contained 16 per cent. of aniline.

180.

Treatment of Bilharzia.

TSYKALAS (*Wien. klin. Woch.*, December 1st, 1921) states that the frequency of bilharzia in Egypt is shown by the fact that 60 to 87 per cent. of the 13 million inhabitants of Egypt suffer from the disease. His practice is to inject intravenously 1.0 to 1.2 grams of emetine in the course of eight to ten days, in doses of 0.1 to 0.12 gram daily. This method has no bad effect on the general condition, whereas the same amount given in smaller doses, such as 0.05 to 0.06 gram daily in the course of sixteen days, or in doses of 0.1 to 0.12 every other day, have had the most alarming results, and have even proved fatal. Emetine not only acts on the cause of the haematuria—namely, the ova of distoma—but also kills the embryos in the ova. The treatment is continued in mild and moderate cases for ten days, in severe cases for twelve days, and in women and children six to eight days. It is interrupted on the eighth day if signs of intoxication, such as diarrhoea or repeated vomiting, occur. If the haematuria does not cease after this treatment, one is justified in concluding that organic changes in the bladder and kidneys are present, for which local measures must be employed. Of 2,000 cases treated with emetine in this way more than 90 per cent. made a complete and permanent recovery.

181.

Morbilli Bullosi.

MORTON (*Brit. Journ. Child. Dis.*, October to December, 1921) records an example of the rare condition known as morbilli bullosi, in which an eruption resembling pemphigus is combined with the ordinary rash of measles. The patient was a girl, aged 7½ years, who was stated to have had measles two years previously. After a prodromal stage of three days, in which the symptoms were headache and a discharge from the eyes, a rash resembling measles developed on the trunk and limbs. On the following day, twenty-four hours after the first appearance of the rash, a bullous eruption developed, beginning on the chest and rapidly spreading in fresh crops to other parts of the body. On admission to hospital, on the sixth day of disease, in addition to a generalized morbilliform rash, the face, trunk and limbs were covered with bullae of all sizes up to an inch in diameter, many of which had ruptured, leaving the epidermis wrinkled and hanging in shreds, exposing deep red patches of bare skin. Death took place on the seventh day of disease. Apart from a bronchopneumonic condition of the right lung nothing abnormal was discovered at the autopsy. All the previous cases of morbilli bullosi have been described by German writers, with the exception of one reported by Neff (*American Journal of Diseases of Children*, September, 1920).

182.

Infantile Amoebic Dysentery.

SPOVERINI (*La Pediatria*, January 1st, 1922) publishes five cases of amoebic dysentery occurring in young children. None of these cases were recognized as such at first, and, although none of the cases were very severe, the disease lasted several months in some of them. The occurrence of amoebic dysentery in places where it had hitherto been unknown is one of the remote results of the war. Contagion clearly occurred through sleeping in a common bed in three cases. As soon as specific treatment (intramuscular injection of emetine hydrochlorate) were given the symptoms soon cleared up. The chief object in publishing these cases is to point out the necessity, in similar cases of mild chronic diarrhoea, of examining for the amoeba.

183.

Saturnine Asthma.

TEDESCHI (*Rif. med.*, November 26th, 1921) reports two cases of asthma which seemed to be causally associated with lead poisoning. The author discusses the various possible ways in which lead might set up asthma, and decides that frequently the so-called saturnine asthma is really a phase of uraemia or of the cardio-renal effects of the poison. But there are other cases of bronchial asthma where the saturnine element is preponderant, and where the lead poison may be looked upon as the chief factor. Such cases are, however, rare.

184.

Treatment of Favus.

ACCORDING to MIRAMOND DE LA ROQUETTE (*Journ. de radiol. et d'électrol.*, November, 1921), favus is very prevalent in Algeria, as was shown by conscription among the natives. Before the war persons affected with favus were excused military service or discharged from the army; but subsequently they were incorporated and special treatment was adopted. During 1921 1,200 natives were treated and cured at the physiotherapy centre at Algiers. Treatment consisted in epilation by electrolysis and daily applications of sulphur and salicylate ointment for six to eight weeks.

SURGERY.**185. Haemorrhage during and after Tonsillectomy.**

COAKLEY (*Journ. Laryngology and Otology*, January, 1922) advocates treating haemorrhage during and after tonsillectomy, whether it be operative, recurrent, or secondary, by ligation of the vessels, and deprecates reliance upon such methods as pressure, styptics, suturing the faucial pillars, etc. The technical difficulty of applying a ligature in the tonsillar fossa is overcome by the use of a straight or curved haemostat with sufficiently long handle, an ordinary Allis haemostat, with four mouse teeth and a 7-inch handle, being the best. When the bleeding point has been secured, a slip-knot is tied in a 14-inch long silk ligature, the loop being just large enough to pass over the handle of the haemostat. The non-slip part of the loop having been grasped close up to the knot by a pair of slightly curved long-handled forceps, the loop is carried by the forceps down the shank and over the end of the haemostat, so as to engage the vessel, when the free end is drawn tight, and the haemostat and forceps are removed. Although only a slip-knot, it is found that when pulled tight it does not slip, and the ends can be cut off close. By having several forceps and slip-knots ready vessels can be successively ligated as rapidly as could be done in an open wound. Recurring haemorrhage within twelve hours, due to imperfect ligation, should be treated in a similar fashion, and especially in patients with cardiac or renal disease, or a high blood pressure, careful watch should be kept for such recurrence. In secondary haemorrhage, arising about the fifth day or later, and due to sloughing, it is more difficult to grasp the bleeding point, and pressure will in most cases control the haemorrhage. In the absence of haemophilia, and even in patients with a prolonged coagulation period, it is claimed that tonsillectomy with ligation of the vessels is a comparatively safe operation, the loss of blood being negligible, post-operative bleeding rare, and, by early detection, easily controlled before serious loss occurs.

186. The Incidence of Cancer in Extreme Old Age.

BERNER (*Norsk Mag. for Lægevidenskab*, January, 1922) has investigated the phenomenon of an apparent decline in the incidence of cancer in advanced old age. He remarks that it would be strange if extreme old age should exhibit comparative immunity to malignant disease. As the following figures show, no such immunity exists; and the apparent decline in the incidence of malignant disease in advanced age is due to the fact that this disease eludes diagnosis more frequently in old age than earlier. The author has scrutinized the records of necropsies at the Ullevaal Hospital in Christiania for the ten-year period 1909-18, and has found that of the 710 cases in which cancer was found there were 113, or 15.9 per cent., in which the disease was not clinically diagnosed. In as great a proportion as 29.3 per cent. the clinical verdict on the cause of death in these cases was debilitas senilis. In 56 cases the persons concerned were over 80, and of these 46.4 per cent. were not known to suffer from malignant disease before death. On the other hand, of the 229 cases in which the patient's age was under 60, only 7.4 per cent. had not been diagnosed as malignant before death. As under hospital conditions nearly half the cases of malignant disease in advanced age were unrecognised before death, it is probable that this oversight is very common in general practice.

187.

Post-typhoid Chondritis.

COTTON (*Boston Med. and Surg. Journ.*, December 22nd, 1921) reports two cases of post-typhoid chondritis of the ribs, in both of which there was a very persistent infection of the wound by *B. typhosus*. In both cases small abscesses developed over the left costal cartilages (fourth and fifth), the pus from which gave *B. typhosus* cultures. The abscesses were excised and the cartilages curetted. A persistent sinus for four months in the first case necessitated a second operation, when all the cartilage and perichondrium from the sternum to the end of the rib was excised and the wound allowed to granulate up. The infection in this case affected a clean cut small area deeply within the rib cartilage, only manifesting itself after perforation and the formation of a secondary abscess. In the majority of such cases the condition arises (as in the second case) in the perichondrium and not inside the cartilage. More frequently such complications subside without coming to operation.

188.

Reinjection of Effused Blood.

THIRS (*Zentralbl. f. Gynäk.*, October 22nd, 1921) has seen no untoward effects in forty patients after subcutaneous injection of the blood which they had lost in abdominal or vaginal operations; haemoglobinuria occurred in none, albuminuria in one only. His method was that of Seifer

and Landgraf; blood lightly expressed from swabs and filtered was mixed with that collected in vessels, was diluted with Ringer's solution in the proportion of two to three, and was administered about three hours after operation. Tibbs also records seven cases of ruptured ectopic gestation in which, after operation, the effused blood, similarly prepared, was re-injected, in part intravenously but mostly subcutaneously. He finds that it is not safe to inject intravenously blood which has been effused for considerable periods of time. It is claimed that satisfactory improvement in the action of the heart is obtained after intravenous injection of comparatively small amounts of blood; the rest should be injected subcutaneously and become slowly absorbed.

189. Cancer and Metastases in Bones.

CATSARAS (*Ann. de méd.*, October, 1921) remarks that metastases in the skeleton are extremely frequent in cancer of the breast or prostate, fairly frequent in cancer of the thyroid and hypernephroma, less frequent in cancer of the uterus, gall bladder, intestine, and oesophagus, and rare in cancer of the liver. As a rule primary adeno-carcinoma of the liver does not give rise to metastases, or if they do occur it is principally in the lymphatic glands at the hilum of the liver, where they follow the course of the lymphatics, or in the lungs via the hepatic veins. These metastases sometimes assume a green coloration caused by the production of bile in the newly formed cells. With the exception of a case reported by Schmidt, Catsaras has been unable to find a single previous case on record of a primary cancer of the liver with metastases in the bones. The case reported by Catsaras was that of a man, aged 65, in whom hepatic cirrhosis was associated with a primary carcinoma of the liver with a metastasis in the upper end of the femur, where it gave rise to a subtrochanteric fracture.

190. A Thermo-Laryngoscope.

SAMENGO (*La Semana Médica*, 1921, 45) describes the instrument, termed by him the thermo-laryngoscope, which he has devised to obviate the necessity of interrupting laryngoscopic observations in order to reheat the mirror after a film of condensed moisture has formed on it as it has become cool. The mirror is warmed continuously by an electric current, obtained from a pantostat or series of dry cells, which passes through the hollowed handle to a small disc-shaped chamber situated behind and in contact with the mirror and containing a suitable resistance. For diathermic or other surgical interventions in the larynx or pharynx the author fixes his instrument in position by means of an adjustable support applied to the head and malar regions of the patient; the surgeon's hands are thus freed. The thermo-laryngoscope (preferably with a mirror of nickel) and the adjustable support permit also of control of helio-therapeutic applications in cases of laryngeal tuberculosis.

191. Treatment of Cold Abscesses with Injections of Cod-liver Oil.

KIJZER (*Nederl. Tijdschr. v. Geneesk.*, November 5th, 1921) states that since the end of 1918 he has systematically treated all cold abscesses by puncture and injection of cod-liver oil, the results being as follows: (1) Rapid healing and formation of a homogeneous creamy pus containing numerous white cells; the pus was always sterile, but the abscess could not be attributed to septic puncture. (2) A slight reaction in the neighbourhood of the abscess shown by the skin becoming redder and warmer. After an initial increase there was a rapid diminution the quantity of pus, followed by formation of connective tissue and cure. Injections of cod-liver oil appear specially indicated when there is a danger of iodoform poisoning, particularly in infants and old persons. The quantity of cod-liver oil injected was about a third to half the amount pus removed by puncture. In addition to pure cod-liver oil Kijzer also employed a 20 to 40 per cent. suspension of sodium carbonate in cod-liver oil, which was of value in gonitis, fistulous tracks being rendered visible in the diagram.

192. Lumbar Puncture in Intracranial Haemorrhage of the Newborn.

STEFANO (*La Pediatria*, January 1st, 1922) says that lumbar puncture is definitely indicated in intracranial haemorrhage of the newborn. It should be practised as soon as possible, and repeated if necessary several times. There is danger if it is done with careful technique. The effect is immediate and remote, and tends to lessen nervous symptoms of encephalic origin. In addition injections of adrenaline, calcium chloride, or normal serum may be given.

OBSTETRICS AND GYNAECOLOGY.

193. Antistreptococcal Serum in Puerperal Fever.

AN exhaustive study of the value of antistreptococcal serum in puerperal sepsis has been made by KRONGOLD-VINAVER (*Annales de l'Institut Pasteur*, December, 1921, No. 12). A bacteriological examination of the lochial secretions of women after childbirth was made within forty-eight hours after delivery by means of a swab taken from the neck of the uterus. The inoculated swab was dipped in a tube of broth and cultures made from this on different media: 626 women were examined and 241 showed the presence of streptococci in the lochial discharges. Puerperal fever never developed among the 385 women from whom streptococci could not be recovered; but amongst the 241 cases showing the presence of streptococci 41 developed a rise of temperature subsequently. Such a series of cases provides strong confirmation of the clinical experience that the streptococcus is by far the most frequent cause of puerperal fever, and, as the author observes, it points to the importance of examining the secretions after labour so that the physician may be forewarned if streptococci are present. The absence of streptococci, on the other hand, may be taken as a reassuring pronouncement. The antistreptococcal serum used for the treatment of these cases was prepared by the injection of a horse with a single dose of living virulent streptococci, the animal being bled a fortnight later; the protective properties of the serum were standardized on mice. For the treatment of cases of puerperal sepsis the serum was injected in doses of 60 c.c.m. subcutaneously for three consecutive days, or 20 c.c.m. diluted with saline intravenously. Of the 41 cases which showed puerperal sepsis of greater or less degree, the author is able to report 38 recoveries as the result of the serum injections, the only method of treatment employed. In only 5 of the cases was the streptococcus recovered from the blood, and 3 of these cases were fatal. In all the cases antistreptococcal serum was injected on the first indication of a rise of temperature, and this early treatment may account for the favourable results. A full history of 43 cases of puerperal fever, with notes on the serum treatment and temperature charts, is given by the author. It is of interest to note that among the 241 strains of streptococci recovered after parturition only 4 were virulent for mice. No parallelism appears to exist between the animal virulence and the haemolytic properties of streptococci and their pathogenic properties for women. This work points plainly to the advisability of a routine examination of the uterine secretions after delivery. If streptococci are present steps should be taken so that, if the patient manifests a rise of temperature, active treatment with antistreptococcal serum may be instituted immediately.

194. Exudative Erythema.

DAVIS (*Brit. Journ. Derm. and Syph.*, January, 1922) records two cases of exudative erythema associated with malignant disease of the uterus. Although pregnancy may be associated with a toxic eruption, the coincidence of a uterine neoplasm with such an eruption has not previously been noticed. In the first case an inoperable spindle-celled sarcoma involved the bladder and uterus, and seven months before the end, an urticarial rash appeared on the forearms, and gradually spread over the abdomen, back, and legs. When at its worst it consisted of circinate patches of erythema with raised edges, and this persisted till shortly before death. The second case presented a widespread irritating circinate eruption, raised at the edges by exudation, and thickest on the extensor aspects of the legs and thighs, but affecting every part except the face, scalp, and the palmar and plantar surfaces. As she gave a history of continuous "menstruation" for two years she was curetted and an adeno-carcinoma found and removed, and with recovery the eruption disappeared. The only other recorded instances of uterine neoplasms causing toxic symptoms are three, reported by Gaston, of alopecia areata associated with fibroids.

195. Abdominal Application of Radium for Inoperable Cancer of the Cervix.

SCHWARTZ (*La Gynéc.*, September, 1921) records four cases of the cervix treated by laparotomy and the application of radium emanation enclosed in a long, to which a linen thread and, enveloping this, an india-rubber tube of 2 mm. diameter were attached, being made to protrude at the lower angle of the abdominal wound and removed after a period of two to five days. The needles were placed (1) in the incised vesico-uterine fold parallel to the anterior surface of the cervix, (2) beneath the recto-uterine peritoneum parallel to the posterior surface of the cervix, and (3) after opening of the parametrium by incision of the round ligaments, in the

actual substance of neoplastic infiltrations or of cancerous lymphatic glands. Subsequently the peritoneum was sutured with care. The total abdominal dose corresponded to from 13 to 54 millicuries destroyed. Vaginal and cervical applications of radium were made at the same time, but might preferably be made, according to Schwartz, at an antecedent séance. In one case, that of a patient with a myomatous uterus, bilateral adnexal cysts and extensive infiltration of the broad ligament of one side, the abdominal radium applications were preceded by subtotal hysterectomy, which by removal of the primary centres of growth would permit, it was hoped, of freer access of the emanation to the more distant foci. One patient succumbed, with symptoms of peritonitis, six days after operation and one day after removal of the tubes.

196. PROUST (*Gynec. et Obstét.*, 1921, iv, 5), using a modified Schwartz technique (see EPITOME, August 20th, 1921, 170), has treated three cases of cervical cancer by intra-abdominal radium applications. The first patient, in whom the broad ligaments of both sides were invaded, and who received application during four days of ten tubes each containing 2 mg. of radium element, followed eleven days later by intra-uterine application of 30 mg. for four days, appeared to be in good health four months later. The second patient, in whom the immediate results were satisfactory, has been lost sight of. The third patient died of pneumonia three months after treatment. Proust remarks that at present intra-abdominal radium applications are only indicated in extremely advanced cases in which a vaginal application sufficiently potent to destroy the tumour cells would be dangerous to the patient.

197. Pelvic Varicocele.

ACCORDING to CASTANO (*Revista Española de Obstet. y Ginec.*, July, 1921), pelvic varicocele may be due to intrapelvic congestion resulting from congenital or acquired syphilis. The subjects most liable to pelvic varicocele are, as a rule, those who eat copiously of meat, are constipated, and have undertaken laborious work before puberty. The condition is characterized by sclerosis of the venous walls and periphlebitis involving the adjacent nerves. In spite of good general health the patients complain of constant discomfort in the vagina, vesical and rectal tenesmus, and premenstrual discomfort; the most characteristic symptom, however, consists in vaginal hypersensitiveness. Leucorrhoea is usual, and menorrhagia is frequently present. On examination tenderness is found in the vaginal fornices, which are rugose, oedematous, and congested; varices are present in the vaginal walls, but disappear in the Trendelenburg position. Early treatment is required, in the author's opinion, in order to prevent the production of uterine and adnexal lesions which later may require hysterectomy. The operative treatment advocated by the author consists in laparotomy, rendering the pelvic veins turgid in order to inspect the lesions, incision of the infundibulo-pelvic ligament, and removal in two centimetres of their course of the venous trunks which accompany the ovarian artery.

PATHOLOGY.

198. Observations on the Significance of Prowazek's Corpuscles in Trachoma.

LUMBROSO (*Arch. des Institut Pasteur de l'Afrique du Nord*, No. 4, 1921) reports a number of observations which he has made to determine the etiological significance, with regard to trachoma, of the corpuscles of Prowazek. These corpuscles consist of certain cellular inclusions in the form of small round or ovoid granules, surrounded by a peculiar envelope, relation to the nucleus. Around them is a reaction on the part of the cell. The regarded as a reaction on the part of the cell. The corpuscles themselves were described in the first place by Prowazek and Halberstedt as chlamydozoa and were held to be specific to trachoma. In all, 87 cases of conjunctival affection have been studied, including trachoma, blenorrhoea of both gonococcal and non-gonococcal origin, neonatorum of both gonococcal and conjunctivitis due to the phlyctenular conjunctivitis, and conjunctivitis due to the Koch-Weeks bacillus and to the bacillus of Morax-Axenfeld. With regard to trachoma, the corpuscles were found in 63 per cent. of recent cases and in 15.8 per cent. of cases which had passed into the cicatricial stage. On the other hand, in cases of blenorrhoea neonatorum of non-gonococcal origin they were never found to be absent. In no other conditions could their presence be demonstrated. From these experiments he comes to the conclusion that the corpuscles represent the etiological agent of a specific conjunctival infection which is frequently associated with recent cases of trachoma. When it occurs under these conditions it furnishes an example of a

mixed infection. It seems probable that the actual disease initiated by this agent is none other than blenorrhoea neonatorum, judging from its constant presence and peculiar abundance in this disease. It is only fair to say that not too much stress should be laid on this opinion, as no more than five cases of this affection appear to have been examined.

199. An Intracutaneous Reaction for Tuberculosis of the Skin.

BUSACCA (*Wien. klin. Woch.*, November 24th, 1921) states that studies on anaphylaxis have shown that tuberculous subjects are hypersensitive to normal horse serum. It therefore occurred to him that he might avail himself of this fact for the diagnosis of tuberculous skin lesions. As it was desirable to avoid a violent general or local reaction, the intracutaneous method of inoculation appeared a suitable method. The investigation was carried out first with 0.1 c.cm., and later with 0.2 c.cm. of normal horse serum. A positive reaction was shown by the appearance round the site of injection of an erythematous area, with an infiltrated centre showing one or two vesicles. The reaction reached its height in twenty to twenty-six hours, and disappeared without leaving a trace within forty-eight hours, though in very marked cases it might persist for two or three days. General symptoms were never observed, and the injection did not cause the patient any more pain than other intracutaneous injections. A positive reaction was never found except in cutaneous tuberculosis and lupus erythematosus, the exact figures being as follows: Of 119 cases of cutaneous tuberculosis, 94, or 80 per cent., were positive; 18, or 14 per cent., negative; and 7, or 6 per cent., indefinite; of 4 cases of lupus erythematosus, 1 was positive and 3 negative. Three cases of pulmonary tuberculosis all gave a positive reaction. The reaction was more intense in the initial stage than in advanced cases, in localized than in diffuse forms, and in active than in torpid forms. The superiority of the reaction over von Pirquet's test was that the horse serum reaction was only positive when the disease was fully developed. Its sole drawback was that it was positive in only 87 per cent. of the cases of tuberculosis, but it is generally known that the ordinary tuberculin reactions are positive in 90 per cent. only, irrespective of the form of the disease in which they are used.

200. The Oculo-Cardiac Reflex in Tuberculosis.

THE oculo-cardiac reflex, which is obtained by observing the effect on the blood pressure and pulse of pressure on the eyes, has been made the subject of an investigation reported in the *Gazette des Praticiens* (January 1st, 1922). In a normal response the pulse is diminished four to twelve beats per minute, but it is well known that in cases of hypersecretion by the thyroid the pulse may be slackened by more than twenty beats per minute by pressure on the eyes. The authors of the present investigation report that in mild cases of tuberculosis the reflex is normal. In more advanced cases with impregnation of the system with tuberculous toxins, although the defensive mechanisms may be adequate, a disturbance of the sympathetic system is manifested by an abnormal oculo-cardiac reflex. In such cases the reflex is usually exaggerated, the pulse being slowed twelve to twenty beats. On the other hand, in the presence of more marked intoxication with insufficient defensive response the general hypotonic condition of the sympathetic system is characterized clinically by an abolition of the oculo-cardiac reflex. Although the response to this reflex is not to be taken as an absolute index of the patient's resistance to the infection, yet the authors suggest that the reaction may be of value from the point of view of prognosis. The reaction is not on a par with immunity tests such as demonstrate the presence of protective substances in the blood, but is an indication of the extent of intoxication or severity of the disease.

Muscular Tonus.

201. BAX'S (*Arch. de méd., cir. y esp.*, November 15th, 1921) state that it has been definitely established by recent investigation that there are two perfectly distinct elements in muscular activity. This physiological duality has a corresponding anatomical basis, and the organs and nervous system which regulate both are perfectly distinct. Voluntary muscular contraction represents the kinetic element of muscular action. Its organ is the muscular fibre and its nervous system is the general sensori-motor system or pyramidal tract. Tonus, on the other hand, represents the static element of muscular contraction. Its organ is the sarcoplasm and its nervous system a complex structure known as the extra-pyramidal system. All forms of voluntary kinetic activity have their equivalent in static involuntary activity. While in physiological condition both forms of muscular activity are independent, in hand, certain pathological changes may disturb them and give rise to syndromes characterized by disturbance of muscular action.

Some Observations ON THE INVESTIGATION OF THE TOXAEMIAS OF PREGNANCY.*

BY

PROFESSOR A. LOUISE NEILROY, M.D., D.Sc.,
DIRECTOR OF THE OBSTETRICAL AND GYNAECOLOGICAL UNIT, LONDON
SCHOOL OF MEDICINE FOR WOMEN.

Of late years much stress has been laid upon the great value and benefit to be derived from the medical supervision of the pregnant woman, not only to herself but to the future welfare of her child. It has been proved by experience that attention to the disorders of pregnancy has brought about a considerable reduction in foetal mortality, and of the complications of labour and the puerperium.

The subject of pre-natal care is very closely bound up with that of infant mortality, as child life begins at the conception of the ovum. The medical profession owes a debt of gratitude to the work of Dr. Ballantyne of Edinburgh, as he gave the first stimulus to the interest in ante-natal hygiene and pathology, and it is due to his enthusiasm, and also to Dr. Amand Routh, that we are now alive to the vast and far-reaching importance of the subject.

Obstetrics having been rescued from the hands of the untrained midwife is now a science which has advanced more rapidly than almost any other branch of medicine.

Now, when every possible surgical method has been exhausted for alleviating childbirth, we turn our attention to the medical aspect of the subject to find that the work of the future lies in the investigation of the physiological and pathological conditions of pregnancy. By the prevention or early relief of many conditions we will soon realize that much of the operative interference advocated hitherto is unnecessary, and that by reducing the number of operations at childbirth much will have been done to diminish the maternal and infant mortality.

For the same reason puerperal sepsis will be found to have a close association with the prevention of abnormal conditions found during pregnancy.

The main work of the future lies in the investigation of the toxæmias of pregnancy. At present we only stand on the threshold of the subject and contemplate as if in a mist the difficulties and complications which confront us. Already the literature is burdened with inexactitudes, published by physiologists and pathologists who not only contradict one another but themselves in their subsequent publications. Such a condition of affairs proves the difficulties of the research. Clinicians look for guidance to the laboratory workers, but much patience will be required before the problems involved are ready for solution. Take, for example, the ammonia coefficient in the urine of pregnancy, which was looked upon as an almost infallible test of the gravity of the condition, and was employed as an indication for the termination of pregnancy. It is now admitted that it is of little value, as it is so readily modified by various factors, such as diet, vomiting, and the administration of alkalis. One discovery of vast importance is that the clinical obstetrician can no longer stand alone in his diagnosis of the complications of pregnancy, but that he must have help from various sources. The main source of help is to be found in (1) public authorities, and (2) expert laboratory workers.

1. Public Authorities.

The first named must give facilities for the observation of patients in ante-natal clinics, both outdoor and indoor, either in connexion with maternity hospital centres or associated with them. The Ministry of Health has done much to advance obstetrics, and its department of maternity and child welfare, under the direction of Sir George Newman and Dr. Janet Campbell, has raised the standard of obstetrics throughout the country. Ante-natal and child welfare centres are given grants towards their upkeep, and their work is organized and inspected. The centralization of the work is the first step in the establishment of the fact that obstetrics is a branch of the work of the public health authority.

The maternity allowance enables the working-class mother to be freed from financial anxiety, and to have skilled help and attention when required.

Maternity hospitals not only benefit their patients directly, but provide material and facilities for the training of students and midwives, who are thus made fully aware of the importance of the subject of child welfare from its ante-natal beginnings.

2. Expert Laboratory Workers.

Well-equipped laboratories are required for the investigation of ante-natal conditions; such laboratories should be within reach of all maternity hospitals and obstetricians. The great difficulty at present is the problem of finance—a serious question, and one which must be overcome if British research workers are to maintain their place with other countries.

Grants can be obtained from the Medical Research Council and other scientific bodies, such as the Royal Society and British Medical Association, but even these are threatened with the Government economy axe, authorities being unmindful of the fact that true anti-waste conditions are brought about by the provision of healthy children who will not become a subsequent burden upon the State.

The Physiology of Pregnancy.

Before entering upon a discussion of the abnormal conditions found in pregnancy it must be noted that very little is known of the normal physiological processes which take place in connexion with the physiology of reproduction and the newborn; and that a great deal of research must be carried out in these directions before we can dogmatize as to where the normal ends and aberrations begin.

The Medical Research Council is the first organized research centre of its kind in this country, and its results will be of value since it co-ordinates the work of so many investigators. Ideas should be centralized and special lines of research organized, and workers should not remain isolated and scattered in laboratories. Committees composed of obstetricians and laboratory workers should be formed to draw up schemes for investigation, and mutual help should be given in the supply of information and material.

Public health authorities and societies should appoint committees to investigate and report upon subjects requiring further work. This has been done on several occasions recently by the Obstetrical Section of the Royal Society of Medicine with very satisfactory results, and it is a step in the right direction.

Scheme for the Investigation of the Toxaemias of Pregnancy.

At present much research is being done in various teaching centres upon the origin of these toxæmias. An outline of the scheme carried out at the Royal Free Hospital may serve as an example of such work.

In connexion with the obstetrical unit of the hospital, where whole-time specialists are employed, the patients first come under observation in the ante-natal outdoor clinics, which are held four times a week. The majority of the patients are entered for admission to the wards for their confinement when it is due. The cases are examined and the appropriate treatment given, and when the patient eventually enters the obstetrical indoor department her ante-natal case sheet is incorporated with that of the ward. Before dismissal from the ward after confinement each patient is seen by one of the senior obstetricians and her condition noted on her case sheet. She is given a card to attend at least once at the post-natal clinic should any complications arise and when she is not under the supervision of her own medical attendant. The baby is brought to the infant welfare clinic, and there kept under observation if necessary. A trained sister is available for visiting the babies in their homes, and an untrained visitor keeps a register of the patients and their home conditions, and visits them when required. In this way the patients are kept under observation during the ante-natal and post-natal periods. The infant welfare clinic with its physician in charge, and also the V.D. department, work in close co-operation with the obstetrical unit. In this way the various departments are linked up, and the patients have the benefit of responsible specialists. The obstetrical and gynaecological unit is therefore enabled to devote its entire time to its own special branch. Accommodation for the reception of indoor ante-natal patients is limited. Although these cases require observation to a certain extent it should be possible to carry

* The substance of a paper read at a joint meeting of the Nottingham Division of the British Medical Association and the Nottingham Medical-Chirurgical Society, January 18th, 1922.

this out in rest homes where the cost of upkeep is less than in a large general hospital, and where a purer atmosphere and surroundings might be available.

Cases diagnosed as toxæmic at the ante-natal clinic are admitted to the wards for further investigation and treatment. When admitted a routine method of procedure is carried out; the patient is put at absolute rest in bed and given a carefully measured diet. The urine is collected by catheter for six, twelve, twenty-four hours, and with the blood is sent to the Physiological Department of the London School of Medicine for Women, where an analysis is carried out by Dr. Pilman Williams—a Medical Research Council Scholar—and by members of the staff under Professor Winifred Cullis. The Wassermann test is done as a routine in a very large number of cases in the outdoor department. A general scheme of treatment is carried out for those toxæmia cases which will be referred to later, and it is hoped to publish the results of the investigation of the toxæmias at a future date.

Manifestations of the Toxæmias of Pregnancy.

The developing ovum causes physiological changes to take place in the maternal organism, the evidence of which is to be found in the breast, blood serum, and endocrinous organs. These changes are said to be due to enzymes or ferments circulating in the blood and having their origin in the trophoblast and foetal portion of the placenta. Antibodies are generated in the blood at the same time which render these ferments or toxins harmless by neutralizing them. In this way auto-intoxication is prevented and the woman is immunized by her own serum. These chemical substances were investigated by Abderhalden as the result of Veit's work on the syncytial fragments found in the blood stream in pregnancy, and which are said to be destroyed by antibodies. The ferments have not as yet been isolated as far as any chemical test can be applied to their recognition, but the theory of their presence is supported by a considerable amount of circumstantial evidence. Abderhalden found by his dialysing process that from the sixth week of pregnancy until after delivery these substances could be found in the blood, but his work has been questioned by subsequent observers who obtained similar results in cases of myoma and cancer. The presence in the blood stream of syncytial fragments with villi is borne out by the *post-mortem* examination of patients dying from eclampsia where emboli composed of these structures have been found in the lungs, and also in cases of chorion-epithelioma, where there is a widespread distribution of the malignant growth fragments from the ovum. As far as our present knowledge goes the main source of the toxins is the foetal placenta, the foetus itself contributing little by its waste products to the supply. Abderhalden did not find these substances in the foetal circulation. Under normal physiological conditions the toxins when neutralized are eliminated by the various excretory channels, more especially the kidneys. If the normal process of excretion is interfered with, or if pregnancy has occurred under conditions where elimination has been defective, as, for example, in nephritis, a condition of auto-intoxication or toxæmia may result; its severity depends upon the strength and degree of concentration of the toxins and on the failure of the maternal organism to excrete them. Accumulation of toxins occurs should there be any interference with the metabolic processes of the liver, as this organ, together with the endocrinous organs, detoxicates the ferments to a certain extent and renders them innocuous when passing through the excretory channels. The liver is therefore a most important organ in the investigation of those toxæmias which are intimately concerned with its function. The kidney is secondary and acts as an excretory organ, its degree of activity depending upon its previously healthy condition and upon the virulence of the toxins which pass through its tissues. As the toxins are retained in the blood, the chemical analysis of the blood is as important as that of the urine. It is said that toxins having their origin in the syncytium are more active in the early months of pregnancy, but this is open to question, as it is a matter of clinical experience that severe toxæmic conditions, such as are found in eclampsia and accidental haemorrhage, occur in the late months of pregnancy. As investigators advance in their researches wider fields seem to open out, and conditions such as haemorrhage from the pregnant uterus, formerly looked upon as due to local or traumatic causes, are now classified under toxæmias. The majority of cases of interruptions of pregnancy—that is, abortion, premature births, habitual death of the foetus, etc.—are now looked upon as toxæmic in origin.

Gordon Ley² found that a large number of cases of accidental haemorrhage showed toxic symptoms. The toxæmic origin of eclampsia is now accepted, and also of persistent vomiting, chorea, ptialism, acute yellow atrophy, and insanity.

It may be possible that in the future we will find conclusive evidence that fibroids are due to a toxin in the blood. The investigation of several cases of this condition has led me to adopt this view of the origin of these overgrowths of the uterine wall, associated as they frequently are with severe haemorrhage which is not mechanical, and also with toxæmic complications. There is histological evidence to prove that there is some chemical irritation of the walls of the blood vessels in the substance of the growth, more especially in cases of multiple small tumours. It is quite possible that such conditions as hydatidiform mole also may owe their origin to some toxic condition of the ovum.

It is difficult to distinguish a toxæmia of pregnancy in a previously healthy individual from that of a pregnancy super-added to an already existing disease. This question affects the prognosis and also the advisability of incurring a future pregnancy. The history of previous constipation, intestinal stasis, hepatic or renal disorders is a guide. Examination of the teeth for evidence of caries or pyorrhoea, and x-ray investigation of the stomach and bowel are of value, as also the investigation of the bacteria of the bowel contents and the urine. As a rule the toxæmias of pregnancy disappear after labour. Little is known of the changes which take place in the endocrinous organs in pregnancy or of their failure in function. Epidermal changes such as pigment deposit, dry scaly skin, brittleness or loss of the nails, with thinning of the hair, point to thyroid and suprarenal insufficiency.

The Urine in Pregnancy.

The routine examination of the urine in pregnancy is essential in every case; when albumin is found to be present it should be looked upon as a danger signal, although it must be remembered that some of the most serious cases of eclampsia and coma have shown no evidence of albumin previous to the onset of the acute condition.

Albuminuria may be a transient symptom, it is not always evidence of toxæmia. It is most frequently found in the latter half of pregnancy and in primiparae. It may be associated with death of the foetus and premature labour. If the amount of albumin is considerable the possibility of the occurrence of eclampsia must be borne in mind. When associated with oedema of the abdomen and lower extremities it points to toxæmia. If there is oedema of the face and arms the condition is more likely to be one of chronic nephritis (Eden). In some cases the toxic symptoms disappear after death of the foetus in the uterus; the toxæmia resulting from infection of the dead ovum must not be confused with the toxæmias due to placental origin. In some cases of toxæmia oedema of the foetus has been found and pathological changes in the placenta.

What is the value of the analysis of the amount of the various constituents of the urine? Mackenzie Wallis³ lays much stress upon the diastase content of the urine and blood, and advocates that the test should be made, together with the urea concentration test by Maclean's method, the ratio between the amount of globulin and albumin, and the urea content of the blood. He also investigates the blood for sugar, and when possible the cerebro-spinal fluid also. He holds the view that globulin is a direct indication of the amount of toxin eliminated, and is therefore more favourable than albumin excretion. In the urea concentration test 15 grams of urea is given to a fasting patient, and the urine examined in two or three successive hours. If the amount of urea is found to be 1 per cent. or below, damage to renal tissue is taking place; the normal amount should be 2 per cent. or more.

Mackenzie Wallis affirms that diastase is a constant factor in the urine of the non-pregnant, except in cases of disease of the pancreas, but that it is affected by toxins in pregnancy, the urine showing a high diastase content in eclampsia and other toxic conditions. This is an important danger signal if the rise in content is rapid; it sometimes persists after other symptoms have disappeared. Congestion of the capillary tufts of the glomeruli is followed by a rapid rise in the diastase content of the urine. The content is usually low in chronic nephritis—below ten units—and is therefore a means of distinguishing between the two conditions.

The nitrogen changes are of importance. For the meantime

an ammonia coefficient has to be left in abeyance. Urea is diminished in eclampsia and in persistent vomiting. Acetone is only of importance when associated with diacetic and oxybutyric acids; if these are in excess in the blood there is a condition of acidosis present. Williamson⁴ has found acidosis constantly present in severe toxæmia with albumin, but not in chronic nephritis unless toxæmia is added.

The excess of acid in the blood is neutralized partly by the ammonia or alkaline blood salts. The liver being concerned with carbohydrate metabolism is an important factor and when destruction of its tissue occurs the condition is grave. Lipoid substances are found in the blood in hepatic derangements.

The Blood.

It is essential to examine the blood in order to determine the amount of retention of the various products of disordered metabolism. The concentrated toxins of pregnancy seem to have an effect upon the tissues similar to those of some forms of snake poison. According to Mackenzie Wallis the blood changes in toxæmias are not marked. Blood sugar shows little change, and this he takes as evidence of the slight disturbance of the endocrinous organs. Blood diastase is unchanged in eclampsia but increased in nephritis. A high urea content indicates progressive destruction of kidney tissue, and in such cases induction of labour should be considered. If the urea content rises to 0.3 per cent. there is grave danger to the patient.

The Wassermann reaction has been investigated in the obstetrical department of the Royal Free Hospital in a very large number of cases by Dr. Pilman Williams, but it has been found that the results are somewhat unreliable as compared with

Positive results alternate with periods of pregnancy, and do not give evidence of the presence or absence of syphilis. It is quite possible that there is a reaction in pregnancy which may influence the Wassermann test.

In the diagnosis of toxæmia from nephritis there is much confusion and difficulty. The factors which have been put forward as a means of differentiation are: The diastase urine content is high in toxæmia, low in nephritis, while in the latter the blood content is increased. Serum globulin is more abundant in toxæmia, and serum albumin in nephritis. Acidosis is present in toxæmia, and rare in nephritis. Albuminuric retinitis is more frequent in nephritis. Primiparae suffer more from toxæmia, and nephritis is more frequent in multiparae.

The rise in blood pressure is a valuable danger signal, and in threatened eclampsia is often the forerunner of convulsions. If it rises above 150 mm. there is cause for anxiety. A high blood pressure persisting in spite of treatment is sometimes an indication for the termination of the pregnancy. It is associated with the function of the pituitary and suprarenal glands, and with the presence of amines.

Changes in the Tissues.

Bacteriological investigation of the toxæmias has contributed little to their elucidation. The histological examination of organs obtained *post mortem* and the examination of the placenta show destruction of renal and hepatic tissue

Changes in the uterus. Gordon Ley, who was present, concluded that the condition was due to toxæmia; he found marked degenerative changes in the uterine wall, with areas of necrosis, haemorrhage, and oedema of the connective tissue, and diminished elasticity, showing a tendency to rupture.

It is probable that cases of rupture of the uterus will be found to have their origin in toxæmia; this theory explains the ease with which rupture takes place after slight manipulation of the uterus, and the resistance of a healthy organ to strain in cases such as impacted shoulder presentations. The cause of atonic *post-partum* haemorrhage may be found on examination of the blood and urine. Changes in the placenta have been observed by numerous workers. Persistent vomiting and eclampsia may be taken as examples of the early and late toxæmias; the clinical histories of such cases and the *post-mortem* findings point to a variety of toxins as a cause. In time it may be possible to group the toxæmias of pregnancy into various classes corresponding to the duration of pregnancy. It is also likely that it will be possible to draw a distinction between those cases in which the liver is involved, and others in which there is deficient elimination

by the kidneys. The investigation of the sugars in the urine and blood of pregnant women opens up a wide field for research upon carbohydrate metabolism and toxæmias.

General Principles of Treatment.

The aim of treatment is to neutralize and dilute the toxins in the serum, and to facilitate their elimination by the normal channels of excretion. Rest in bed is essential in the severe cases, as it prevents tissue waste and favours diaphoresis and kidney excretion. A protein-free diet is essential in most cases, and Tweedy and others have found starvation of benefit in severe cases of persistent vomiting and eclampsia. It must be remembered that this method of treatment cannot be unduly prolonged as there is a possibility that acidosis may occur. It is sometimes possible to follow up the treatment by a carbohydrate and protein diet without much interval.

I cannot lay too much stress upon the importance of attention to the teeth. Pyorrhoea should be treated by antiseptic mouth-washes and vaccines, and carious teeth attended to or removed. Experience has shown that the treatment of the teeth gives most satisfactory results in the prevention of the severer forms of toxæmia.

Fluids, alkaline if possible, should be given in all cases of toxæmia. If the condition is severe, all stimuli such as noise and light should be excluded. Purgation must be used with caution so as not to cause irritation of the bowel wall; the days of drastic treatment by croton oil happily are over. Paraffin for more prolonged treatment is of great benefit, as it lubricates the bowel contents, prevents the absorption of toxins, and carries down the bacteria in its substance. The colon, which is the main channel for absorption, should be emptied at frequent intervals by enemata given by means of a long rubber tube at low pressure. Intestinal lavage with saline and sodium bicarbonate (5 ij to the pint) is essential in every case, and the slow method of introduction gives the best results, care having been taken to remove the faecal contents from the lower bowel. It must be remembered that such treatment may in rare cases cause uterine contractions and expulsion of the ovum. The continuous drop method of introducing saline and glucose (2 oz. to the pint) into the rectum is of benefit. In severe cases lavage of the stomach, leaving in a full dose of magnesium sulphate, gives good results. Stimulation of the skin is brought about by baths, radiant heat, and packs. Drugs are of little value. For mild cases intestinal disinfectants, such as thymol, cresote, salol, and small doses of calomel, are of benefit. Potassium chlorate gives good results in cases of repeated abortion (Jardine).

Veratrine for the reduction of blood pressure is advocated, but only one dose should be given. Pilocarpine has been abandoned by most obstetricians as it causes oedema of the lungs. The administration of morphine in eclampsia is still a matter of controversy, although the Dublin school by long experience testify to its good results. It is of great use in diminishing fatigue in cases of prolonged vomiting, and its sedative action undoubtedly outweighs its supposed harmful effects. In some cases of toxæmia with high blood pressure I have had good results from the administration of Dover's powder in 5-grain doses. I have had no experience of de-capsulation of the kidneys, nor do I consider this treatment advisable in view of more modern methods. Venesection is advocated in eclampsia, and is of great benefit in cases of full pulse and raised blood pressure. It is contraindicated in cases of anaemia and exhaustion, such as is produced by persistent vomiting. Alkalinized saline transfusion is employed as a means of neutralizing and diluting the toxins in the blood stream. Mild cases of toxæmia respond readily to treatment, but in the experience of most obstetricians in some severe cases, especially if of sudden onset, all treatment has seemed useless.

The Interruption of Pregnancy.

The decision as to the advisability of induction of abortion or premature labour is difficult.

Induction is a confession of failure in treatment, and although the toxins are generated in the placenta and therefore removed in most cases by expulsion of the ovum or placenta, it is not always the case that cure results, and it must also be borne in mind that surgical interference carries with it a degree of risk and possibly the termination of the life of the child when pregnancy is advanced. The process of labour throws an additional amount of toxins into the blood stream. In devitalized conditions the risk of sepsis after any

manipulative interference is not to be ignored. In conditions such as threatened eclampsia with rising blood pressure, persistence of albumin in the urine after treatment, or in those in which the urine is diminished or suppressed, induction is indicated. In persistent vomiting, where there is evidence of exhaustion, with signs of liver and kidney destruction of tissue, as in jaundice and vomiting of blood, the termination of the pregnancy is justifiable. In acute conditions labour sometimes occurs spontaneously at the time when the medical attendant is considering its advisability. The administration of an anaesthetic calls for serious consideration, owing to the action of chloroform upon metabolism and the oedema of the lungs sometimes found after ether anaesthesia. If retinal changes occur or opacity of the lens, as in glycosuria, induction should be considered.

The method employed should be determined in each individual case. In early pregnancy laminaria tents may be employed. Premature labour may be induced by bougies or by the introduction of the soft rubber stomach tube into the uterus. Abdominal and vaginal Caesarean section may be selected for some cases, but these operations are associated with a degree of shock, anaesthesia is deep, and the results in severe cases are not always satisfactory.

Conclusion.

In conclusion, we must bear in mind that the main number of severe cases are preventable if treatment can be given in their early stages. Every pregnant woman should be kept under medical observation, and every case of albuminuria should be investigated. Every premature birth should be notified, no matter at what period of pregnancy, and facilities should be given for examination of the ovum. The public health authorities should take up the question of toxæmia of pregnancy just as they have taken up the question of syphilis. Ante-natal beds should be provided in all maternity hospitals. Financial facilities should be given to research workers, especially in the domain of physiology, for the investigation of the normal function of human pregnancy.

Inaugural Lecture

ON

TUBERCULOSIS IN WALES.

BY

PROFESSOR S. LYLE CUMMINS, C.B., C.M.G., M.D., LL.D.,

DELIVERED ON ASSUMING

THE DAVID DAVIES PROFESSORSHIP OF TUBERCULOSIS IN THE
WELSH NATIONAL SCHOOL OF MEDICINE, CARDIFF.

THERE are one or two fundamental conceptions referring to the general question of disease that must be comprehended and borne in mind before it is possible to approach the special problems of tuberculosis with any hope of understanding them. Two essential elements must be taken into account whenever the human body is invaded by bacterial disease. The first is the invasive power of the germ—that is to say, the degree to which it can establish itself and multiply in the human host. The other is the power of the human host to resist or react against invasion. Bearing these two essential factors in mind, we reach another fundamental consideration, which is that the number of germs that can enter the body at the time of invasion is limited, and very much inferior to the number that must finally exist in the infected body when the disease is fully established. From this it follows that in resisting invasion, the body has usually to deal with a number of germs that is relatively small in comparison with the number that it has to deal with when it attempts to cure itself from the established disease. These conceptions are of the greatest importance because they imply that during the progress of an illness the body must gradually gain a much greater power of dealing with the germs than it possessed at the beginning. Were it not so recovery would be impossible.

In an acute disease such as typhoid fever the sequence of events is briefly as follows. A relatively small number of typhoid bacilli succeed in establishing themselves in the body. The body, having had no previous experience of typhoid bacilli, has not developed any considerable power of resisting their growth, and consequently they increase and multiply with great rapidity until, after a given time, usually about ten days, they have reached such numbers that they are able to excite the first well-marked symptoms of the disease. By

this time they have gained an ascendancy over the body, and in fatal cases this ascendancy is maintained until the patient dies. But what happens in favourable cases? The ascendancy momentarily gained by the bacilli is soon lost owing to the successful mobilization of the resisting powers of the body. The symptoms take a turn for the better, the patient becomes less toxic, and in an astonishingly short space of time is convalescent and well on his way to recovery. Remember that at first his body was so lacking in resistance that even a relatively small number of germs could successfully invade it. At the height of his disease his blood and internal organs were teeming with myriads of bacilli, and yet, although unable to resist the small initial invasion, this same patient in the course of three or four weeks has reached a position in which his resistance is able to clear his blood and tissues of myriads of invaders that had multiplied unchecked during the first week or so of the disease. The power of the human body to defend itself is so well established that it can be exploited in prevention, and the use of antityphoid vaccine proves to us that even a dose of killed typhoid bacilli is sufficient to evoke an effective mobilization of the resistant powers of the body, with the result that subsequent invasion by the living germ becomes almost impossible while the immunity endures.

This story of invasion of the unresisting body—virgin soil to the germ—with the subsequent acquisition of sufficient resistance to lead to cure, tends to be repeated throughout the whole list of diseases that are caused by bacteria. But while the fundamental factors are the same, there are great variations in their manifestations in different instances. It is unnecessary to remind you how very different the course of tuberculosis usually is to that of typhoid fever. So different are these two diseases that many find it difficult to believe that, apart from the differences in the causative agents, the same kind of pathogenic machinery is operative in both. Yet there is no doubt that such is the case.

It must be admitted at once that while the story of typhoid fever is, in its main events, retold in nearly every case of the disease, the same is not true of tuberculosis. The manifestations of activity by the tubercle bacillus in its human host are of infinite variety. There are, however, certain points that all these manifestations have in common, and I shall now endeavour to formulate a few of the outstanding characters of the process of invasion by this germ.

To begin with, it can reach the human tissues by several different paths of entry, but the commonest is the breathing apparatus. The germ is usually coughed or spat into the air by sufferers from the disease, and is breathed in by the victim along with the dust or cough-spray that gets mixed with the air drawn into his lungs. In typhoid fever there is usually one definite invasion followed by a short period of multiplication or incubation, usually from seven to ten days, before the symptoms appear. In tuberculosis the process is much more gradual. In the first instance a few germs may be breathed in and may pass through the surfaces of the air pass, but they cause much focal reaction, finally reaching the

But these few will soon be followed by more, sometimes few, sometimes many, because tuberculosis is not usually contracted at one sitting, but through more or less prolonged association with an infected person. The next stage is one of gradual multiplication in the lymphatic glands, or perhaps in the tissues originally invaded; and this multiplication is unaccompanied at first by any considerable degree of general reaction. The body tends rather to devote all its powers to shutting in the invader and holding him down at the place where he has landed. Here there is no question of a few days. A much longer period—months or even years—may elapse before the germs have multiplied sufficiently to cause obvious symptoms and recognizable signs.

Invasion, then, is usually a matter of frequently repeated entries and gradual multiplication in a few sites, the body attempting to shut the germs in by building up defensive walls around them. It is the momentary breaking down of these defensive walls that leads to a sudden invasion of the rest of the body by a much larger number than it can conveniently deal with; and in this lies the explanation of the periods of acute illness that punctuate the history of chronic tuberculous disease. The process of invasion, then, is slow. What of the processes of reaction? These too are slow. Compared to what takes place in typhoid, the action of the germs and the reaction of the body are relatively slight, although both, acting over a long period, may finally lead to far more destructive effects. Where the initial invasions have

seen too frequent and too large, the bodily resistance will usually fail to be effective and the patient will go from bad to worse. Fortunately, however, this is not the usual story. We have the best reason for knowing that in the vast majority of cases the circumstances are so favourable as to allow the body to obtain and maintain its ascendancy from the first, so that the germs are finally localized successfully in a few small foci from which they never emerge. We have reason to think that not less than 90 per cent. of the adult populations of our large towns has, actually existing in the tissues, such old foci of controlled and vanquished tuberculosis; and this victory has counted for them more even than might at first appear. Not only have they limited their infection to small isolated stations in their tissues, but they have gained in the struggle a considerable power of resisting further infection. In other words, they have acquired what we call a relative immunity. This relative immunity, although it cannot guarantee against invasion by a massive dose of bacilli, is still effective in overcoming the small infections which must be so constant under the special conditions that obtain in industrial and urban communities.

It is often said that there is no real ground for believing that relative immunity against tuberculosis can be acquired as the result of infection. A moment's reflection will show that the acquisition of such relative immunity is no longer open to doubt. We have only to note the number of hunchbacks that may be seen any day in good health and able to work, with no defect except the deformity that remains from old spinal tuberculous disease, to realize that resistance against tuberculosis can be, and frequently is, gained after infection.

Let us pause to consider what has happened in these persons. In the beginning small numbers of tubercle bacilli must have succeeded in establishing themselves in their bodies unresisted, because the soil had not yet become habituated to resist them. Some of these germs must have reached the spine and multiplied unchecked, leading to necrosis and breaking down of the bodies of vertebrae. The proof that this actually happened is the bent spine of these deformed persons. And yet the process, though accompanied when at its height by the presence and multiplication of innumerable bacilli, has been controlled and overcome; and slowly the patients have come back to health, retaining only the deformity, which shows how active and successful was the bacterial invasion before victory was obtained.

The old idea that tuberculosis is necessarily a fatal disease is therefore no longer tenable. We now know that under suitable conditions and with good surroundings the human body is usually able to overcome the invasion and return to health. Much depends upon the number of germs that were concerned in the original invasion. Where these numbers are very large the ascendancy of the germs is likely to be maintained from the first, and the body can never outstrip it. In these circumstances the disease can only run a rapidly fatal course. In practice every doctor is familiar with two types—the tuberculosis that goes from start to finish as an acute and fatal process, and the tuberculosis that lasts for years, during which time the victim may be perfectly well able to associate with his fellow creatures and to live a relatively normal and happy life fraught with much greater danger to others than to himself.

But there is a third type, one that the doctor does not see—the case that overcomes an early infection without ever knowing it and remains in good health and endowed with a relatively considerable resistance to the germ. Happily this third type appears to be the commonest of all in our urban populations. The proof of its existence is found at the post-mortem table and by means of tuberculin tests on the living. Nageli and others have demonstrated the presence of healed tuberculous lesions in the bodies of adults dying from non-tuberculous diseases in a very large proportion of those examined, and their observations have been amply confirmed. Tuberculin tests applied to the skin and the eye have served to show that, while the percentage of children that react to these tests is very small, the figure increases steadily with each age group until nearly every adult in a town community gives a positive reaction.

In this natural acquisition of protection against tuberculosis by early and abortive infection we have a beautiful example of the adaptability of man to his environment. As Professor Leonard Hill puts it, "God does not temper the wind to the shorn lamb but the shorn lamb to the wind." The inhabitants of our great towns may be of poor physique; they may compare unfavourably in every respect with the

men of our agricultural districts, but they are able to tolerate exposure to considerable doses of tubercle bacilli, and, when they get the disease, they tend to get it in its slow and chronic form, not in its acute and rapidly fatal variety.

So much, then, for those that have grown up in the urbanized, industrialized, tubercularized communities of Great Britain. But what of those whose early environment has been free from all tuberculous taint? Are such persons to be found nowadays? Yes; we have instances of such persons in the inhabitants of Central Africa, where the tubercle bacillus was until very recently unknown. How do they behave when brought into contact with the germ? The experiences of the African Labour Corps in France give us the answer. In spite of their splendid physique, in spite of good food and clothing, in spite of favourable conditions of housing as compared with the British soldiers fighting in the line, these Africans contracted tuberculosis in appallingly large numbers; they contracted it in the most acute and generalized form, and died of it in a very short space of time.

With these considerations in our minds, let us turn to the question of tuberculosis in Wales. The tuberculosis of the Principality differs from that of England in certain well-defined characters:

1. The mortality rate is, on the whole, higher.
2. The highest mortality, relatively to the numbers of the population, occurs not in the crowded town areas, but in the sparsely populated mountainous districts of the north and west.
3. The mortality tends to the "young adult type," especially in the northern and western areas.
4. Although the mortality is so high amongst the population in general, it is less amongst infants and young children than in England.
5. The clinical type in Wales appears to be more acute than in England.
6. In those parts of Wales where the mortality is highest it does not show, as in England, a close correlation with the mortality from all causes, but outstrips this in a very marked degree, showing that some other factor or factors than faulty hygiene must be at work.

What, then, can be the explanation? Why is it that the simple agricultural folk of north-west Wales die from tuberculosis to a degree far greater than the populations of the crowded industrial cities of Cardiff and Swansea or the big towns of England, such as Birmingham and Sheffield? Is it faulty hygiene? It is undeniable that the houses in which these people live are often very insanitary, but their lives are passed for the most part in the open air, and their physical characters are known to be above the average, whereas many of the inhabitants of industrial cities work all day in crowded factories, and return at night to homes where the conditions are, if possible, worse than in north-west Wales. Faulty hygiene, then, cannot explain the whole problem. Is it a matter of the excessive rainfall common to the areas where mortality is highest? There are many who maintain that this is so, but their arguments are by no means conclusive. Rainfall has the effect of clearing the atmosphere from the unhealthy dust and germs that pervade it. A shower of rain diminishes enormously the bacteria in a given volume of air. Infection, and therefore mortality, should be lessened not increased by rain, though damp may very well lead to the development of already acquired infection.

Is it a question of heredity? No serious student of tuberculosis holds the view to-day that tuberculosis is a hereditary disease. Many still believe that it is associated with an inherited disposition, an inborn tendency to invasion by the germ. Again, many authorities believe in the inheritance of resistance to tuberculosis, not in the inheritance to a disposition to it, and for this hypothesis a better case can be made out. I, however, do not share it. If hereditary predisposition were a factor of importance, the local differences in the mortality rate should be far less marked than they are within communities of common stock. If hereditary resistance played a large part, surely children should display marked differences in susceptibility, and should show a low incidence and mortality in those places where the adult incidence and mortality is low: but children everywhere appear to tend to a generalized type of infection such as is associated with extreme susceptibility, while in Wales a low infantile mortality goes with a high death rate in adults.

Again, it is stated by some authorities that the food of the people of the western counties of Wales is greatly inferior to that of the more prosperous agriculturists of the eastern counties and of the towns; and it is suggested that the high

tuberculosis mortality of the former is due to deficient nourishment. There can be no doubt about the importance of nutritional factors in tuberculosis, and recent research lends support to this; but I find it hard to believe that the fine physique of the peasants of the west and north of Wales is associated with serious food deficiency.

The hypothesis that I would put before you as the most probable is as follows. Where human beings are scattered and isolated, the passing of germs from one person to another is more or less restricted except within the home. A whole household may easily be infected by one of its members, but other households go free alike from infection and immunization. Where, on the other hand, human beings are herded together and constantly associated one with another, the germs carried by each are passed on indifferently to his neighbours in the factory, the tramcar, or the home. But the number of germs so passed on may be, and probably is, relatively small in most cases except in infected houses. In these circumstances what result should one anticipate? In crowded communities there should be in almost every individual some degree of infection with the tubercle bacillus. In the majority the degree of infection should be small, leading to the acquisition of a relative immunity rather than to active disease. The inhabitant of a large city must adapt himself to the bacteria that are so numerous in his surroundings in order that he may live at all. Therein perhaps lies the danger to those who quit the sparsely populated areas to seek the higher pay and the more attractive life of densely crowded towns.

In the history of every community it is the period of transition from an agricultural type of life to an industrial one that is fraught with the greatest danger. In England this transition took place during a period that reached its

climax early in the last century. During this period of transition the tuberculosis death rate in England was high, and the "young adult" type of mortality was common. When the rural and urban populations became more stabilized the tuberculosis death rate began to fall, especially in the earlier adult age groups, and this fall has continued to the present time.

In Wales a similar period has been traversed, but, though the climax has been passed, stability has not yet been reached. Many persons still leave their country homes for London or for the big industrial centres of Wales itself, and many of them get infected with tuberculosis and go home again to die, perhaps infecting a whole household before the end. Still, in Wales, as in England, the tuberculosis death rate is falling rapidly, and the young adult type is giving place to the type of middle-age mortality. All these facts seem to point to the importance of varying degrees of acquired resistance as the essential factors underlying the differences between the tuberculosis of Wales and elsewhere. If these factors are indeed the fundamental ones, if Nature is gradually getting rid of tuberculosis by a process of unconscious vaccination, then we should, in our efforts at prevention, give a great deal of attention to defending children and susceptible persons from massive doses, and we should concentrate research on efforts to discover a safe and efficient vaccine—a very difficult task, but one which may yet be accomplished.

I feel certain that it was the realization of the importance of these problems that led Major David Davies and the Misses Davies to found this chair, and it is in the hope that my work may help to solve them that I assume my new duties as Professor of Tuberculosis in the Welsh National School of Medicine.

THE "BUFFERING" OF BLOOD:

A SUMMARY.

BY

A. V. HILL, Sc.D., F.R.S.,

PROFESSOR OF PHYSIOLOGY, MANCHESTER.

THE "reaction" of the blood—that is, the hydrogen ion concentration (c.H) of the blood plasma—is of great importance to the body, especially in relation to respiration. The reaction of blood removed from the body is not constant; it can be changed by changing the volume of CO_2 which it contains, or by adding acid or alkali to it. The same thing may happen in the normal body—for example, exercise results in an increased production of CO_2 , severe exercise throws lactic acid into the blood, gastric digestion removes hydrochloric acid from it, which has the same effect as the addition of sodium bicarbonate to it. In the normal body, however, the c.H of the blood is not altered much thereby, since the respiratory centre is a very sensitive regulator of the blood reaction; the smallest rise of c.H leads to an increase in the frequency and depth of respiration, CO_2 is washed out and the c.H returns towards its usual level. In its function of maintaining the constancy of the blood reaction the respiratory centre is aided by two factors: (a) the activity of the kidneys, and (b) the so-called "buffers" of the blood. The regulation by the kidneys is necessarily a slow process, though very important, their function in this respect being to remove unwanted acid or alkaline bodies; the rapid regulation often required in ordinary life—for example, during exercise—falls entirely on the respiratory centre, aided by the buffers of the blood.

If acid be added to water, or to a neutral salt solution, there will result an enormous increase in the c.H; if the same quantity of acid be added to normal blood the increase will be much smaller. If a given volume of CO_2 be absorbed by blood its rise of c.H will be nothing like as great as if the same CO_2 had been absorbed by water. This relative insensitivity of blood to added acid or CO_2 is due to the "buffer" it contains. Again, if a given quantity of

acid, or a given volume of CO_2 , be added to plasma separated from corpuscles, the rise in c.H will be less than that caused by the same addition to water, but far greater than that caused by the same addition to whole blood. Thus the "buffering" of blood is due partly to certain constituents of the plasma, but more particularly to certain constituents of the red cells.

In blood there are two chief basic elements, which we will refer to indiscriminately as B, namely, sodium and potassium, combined with various acid radicals, chiefly bicarbonates, chlorides, phosphates and haemoglobin. The phosphates reside mainly, and the haemoglobin entirely, within the red cells. Carbonic acid H_2CO_3 forming bicarbonate BHCO_3 with base B, acid phosphate HBHPO_4 forming alkaline phosphate B_2HPO_4 , and acid haemoglobin H.Hb forming the haemoglobin salt B.Hb , must be regarded as weak, that is, only slightly dissociated acids. The salts of such weak acids, especially of the last two, may be regarded as possessing stores of base B, so that if free acid be added to their solution they surrender some of their base to it, form with that acid a neutral (or almost neutral) salt, while they themselves (being very weak acids) proceed to form the neutral (or almost neutral) undissociated acid. In this way considerable quantities of free acid may be added to a solution of such salts of weak acids, without a considerable rise in the c.H. This is the basis of the action of buffers.

Recent work by Barcroft and his collaborators has shown that, in the average normal man, if the volume of CO_2 taken up by blood be plotted, as in Fig. 1, against the c.H of the plasma, then over the range of importance in the living body the relation is a straight line. The slope of this line is a measure of the efficiency with which the blood is buffered; in the case of pure water the line would be nearly horizontal, since here the solution of quite a small volume of CO_2 makes a considerable increase in c.H: in a "perfectly buffered" solution (if one could exist) the line would be vertical, since here the taking up of CO_2 would not affect the c.H at all. With blood the slope of the line lies between these limits; Fig. 1 shows the v. CO_2 —c.H relation for the blood of the "average" normal man. There are certain small variations

FIG. 1.

normal persons from this average curve, its slope varying ± 25 per cent. and its height by rather more. We will consider the factors at work in causing these variations, a matter of importance clinically, since the same factors may produce more extensive variations in disease.

CO_2 is present in blood almost entirely in the combined form, as bicarbonate NaHCO_3 ; a little is dissolved. The e.H. blood is proportional to the ratio,

$$(\text{dissolved } \text{CO}_2) / (\text{combined } \text{CO}_2).$$

Since the dissolved CO_2 is proportional to the CO_2 pressure we may say alternatively that the e.H. is proportional to the ratio,

$$(\text{CO}_2 \text{ pressure}) / (\text{combined } \text{CO}_2).$$

Now suppose we add bicarbonate to blood, keeping the e.H. constant while we do so by increasing the CO_2 pressure in the same proportion as we increase the total bicarbonate—that is, the combined CO_2 . Then the total CO_2 held by the blood is increased by the amount combined in the bicarbonate added, plus the extra amount dissolved owing to the increased CO_2 pressure. The second amount is very small, since CO_2 is not very soluble, so that the only important increase is that due to the added bicarbonate. The same is true of adding bicarbonate at any fixed e.H., so that by adding bicarbonate to blood we merely raise the v. CO_2 —e.H. line of Fig. 1 by a uniform amount all along, without changing its slope; in other words, the degree to which the blood is buffered is unaffected by the addition of bicarbonate as such. By adding bicarbonate to blood we merely cause an increase in its CO_2 pressure for a given e.H.; the CO_2 pressure in the alveolar air is increased therefore, the respiratory centre slowing the respiration to keep the e.H. constant. Hence variations in the total bicarbonate content of the blood are not responsible for differences of slope, but only for differences of position of the curve in Fig. 1. The variations of slope are due to another cause.

The v. CO_2 —e.H. line of Fig. 1 is much less steep for plasma than for blood, which is natural, since the red cells contain the major portion of the phosphates, and all the haemoglobin, which provide the greater part of the base required to combine with, and so absorb, the CO_2 . If, therefore, some of the corpuscles be abstracted from blood, we may expect the resulting v. CO_2 —e.H. line to be intermediate in slope between the line for plasma and the line for whole blood; the more red cells be left the steeper will be the line, the less be left the less will be its inclination. Hence the differences in the bloods of normal individuals in this respect may be attributed to differences in the number and contents of the red cells.

A steep v. CO_2 —e.H. line, implying a well-buffered blood, will be a characteristic of an individual in whom exercise produces little respiratory distress; a line of little slope we should expect to find associated with dyspnoea. It will be very interesting to study the physiological and the clinical aspects of variations in the slope and position of this line.

THE END-RESULTS OF REMOVAL OF TONSILS AND ADENOIDS.

BY

HAROLD S. SINGTON, M.D., BRUX., M.R.C.S. ENG.,
LONDON.

So much has been written recently on the subject of the operation for the removal of tonsils and adenoids that there may perhaps seem to be little more which can be usefully added. There is, however, one aspect upon which little, if any, stress has been laid—namely, the general practitioner's views upon the effects and the utility of the operation. It is he who is naturally in the best position to judge the end-results, since he is able to observe the patients more intimately and for longer periods than the operator or the consultant can do. Further, it is as a rule the general practitioner who decides as to the advisability of his little patients having their tonsils and adenoids removed, and it is he who has to give the parents the reasons, based upon his previous experience, which lead him to believe that benefit will be derived from the operation.

For these reasons I feel that a summary of the cases which have been under my care during the last few years may

serve a useful purpose. I have included all the children under 10 years of age who have had their tonsils completely removed by dissection (all according to the method originated by Mr. George E. Wagh) and their adenoids removed at the same time. The very striking conclusion which this summary indicates is that, once convalescence after the operation is complete, the child's health is so greatly improved that one has hardly ever had to attend him or her again; and that the child is not so liable to other and fresh illnesses as one who retains this lymphatic tissue.

I append a table of the cases, and must add that in only one instance (Case 34) where I have not subsequently attended the child again have I lost trace of the patient. In the remaining cases I have attended other members of the family and have had the opportunity of seeing for myself the healthy condition of the children referred to. I have purposely omitted stating the signs and symptoms which led me to advise operation because I do not wish to confuse the issue, the point which I desire to emphasize being the very small number of professional attendances on these children subsequent to operation, thereby proving the undoubted benefit that has accrued from the surgical procedure. In only four cases (Nos. 12, 26, 33, 39) had an obvious tonsillitis been observed; in four cases (Nos. 3, 11, 33, 50) a cervical gland was sufficiently enlarged to attract the mother's attention; and in three cases (Nos. 21, 45, 49) chorea or acute rheumatism was the reason for advising the operation. In all the other instances it was the general survey of the case which indicated the treatment.

Summary of Cases.

Case.	Year.	Attendances Previous to Operation	Subsequent Attendances.
1	1911	40 in 20 months	For measles and hernia.
2	"	Weekly for 3 years	For influenza 9 years later.
3	1912	43 in 18 months	Nil.
4	"	26 in 4 months	Frequently for congenital deformity.
5	"	33 in 2 years	Chicken-pox in 1920
6	"	33 in 20 months	Occasionally for uric acid.
7	"	30 in 1 year	Nil.
8	1913	Seen once only	Occasionally for talipes.
9	"	Daily for 2 months	Nil.
10	"	5 in 2 months	Appendicitis in 1920.
11	"	Seen once only	Nil.
12	1914	Seen once only	Nil.
13	"	12 in 2 months	For smallpox and bronchitis twice.
14	"	14 in 2 months	For fissure in ano.
15	"	25 in 2 years	Twice since.
16	"	9 in 1 month	Nil.
17	"	73 in 2 years	For gastric disturbances, 7 attendances.
19	"	19 in 6 months	Nil.
20	"	9 in 4 months	For pertussis in 1915; vulvitis in 1919.
21	"	Almost daily for years	Frequently for "congenital heart."
22	1915	13 in 3 months	In 1919 for astigmatism.
23	"	49 in 5 months	Frequently for asthma.
24	"	14 in 12 months	Nil.
25	"	21 in 2½ years	Nil.
26	1919	21 in 5 weeks	Nil.
27	"	10 in 2 months	Chicken-pox in 1920.
28	"	13 in 2 months	For gastritis and food rash several times.
29	"	12 in 6 weeks	Fractured hammers in 1920.
30	"	9 in 1 month	Two attendances for accidents.
31	"	6 in 3 months	Nil.
32	"	6 in 5 months	For gastritis several times.
33	"	16 in 5 months	Two attendances since.
34	1920	6 in 2 months	Nil.
35	"	15 in 7 months	For warts on hand.
36	"	7 in 3 weeks	For tapeworm several times.
37	"	12 in 3 months	Nil.
38	"	14 in 7 months	Nil.
39	"	15 in 14 months	Nil.
40	"	4 in 3 months	Several times for talipes.
41	"	7 in one month	Several times for talipes.
42	"	20 in 16 months	For gastric disturbance in 1921.
43	1921	3 in one week	Nil.
44	"	6 in 6 months	Nil.
45	"	6 in 4 months	Nil.
46	"	19 in 4 months	Nil.
47	"	21 in 1 month	Nil.
48	"	14 in 3 months	Three times for eczema.
49	"	3 in 4 months	Nil.
50	"	24 in 6 months	Nil.
51	"	37 in 2 years	Nil.
52	"	8 in 6 months	Nil.

In 24 cases, or 47 per cent., no further attendance was needed. In 5 cases, or 9 per cent., attendances were required for gastric or intestinal disorders only; in 4 cases, or 7.5 per cent., for congenital deformity; in 4 cases, or 7.5 per cent., for zymotic diseases; in 2 cases, or 4 per cent., for appendicitis; and in 10 cases, or 19 per cent., for other disturbances unconnected with the throat. Thus there are left only three cases—asthma, congenital heart, and bronchitis—where attendance after the operation for removal of tonsils and adenoids was at all frequent, and in these instances it was very much reduced.

THE AFTER-RESULTS OF 21 CASES OF ILIO-COLOSTOMY PERFORMED FOR TUBERCULOUS BONES AND JOINT DISEASES.

WITH A NOTE ON THE FUNCTION OF THE SHORT-CIRCUITED COLON.

BY

HAMILTON DRUMMOND, F.R.C.S. EDIN.,

SENIOR ASSISTANT SURGEON TO THE ROYAL VICTORIA INFIRMARY,
NEWCASTLE-UPON-TYNE.

A FEW years ago the condition known as intestinal stasis was held responsible for many lesions, and among them tuberculous bones and joints. Arising out of this an operation known as ilio-colostomy came into fashion, and was carried out by many surgeons in this country and America.

The operation consists in dividing the lower end of the small intestine, closure of the distal end, and transplantation of the proximal cut end into the uppermost part of the rectum or lower pelvic colon. The idea was to short-circuit the large intestine so that it would cease to function. This procedure was introduced by Sir William Arbuthnot Lane. Professor Rutherford Morison, with an open mind on this subject, visited Sir Arbuthnot Lane's clinic, and after seeing the operation performed by him, and inquiring into his results, decided to give the treatment a fair trial for septic tuberculous bones and joints.

The cases selected for operation by ilio-colostomy were those which had defied all methods of treatment and were gradually losing ground. The operative technique as advised by Sir Arbuthnot Lane was followed, and is not discussed here, the object of this paper being, first, to follow up the late results of twenty-one of the cases operated upon as regards the general health and the local condition; secondly, to ascertain how the functions of the colon had become modified by the operation after the lapse of a number of years.

Table of Cases.

No. and Initials.	Age.	Primary Focus for which Ilio-colostomy was Performed.	Results.
1. M. W.	15	Tuberculous hip, infected.	Well and healed 2 years later; since then cannot be traced.
2. T. H.	7	" "	Well and able to work. See attached note.
3. R. B.	8	" "	Died 7 years later.
4. T. M.	7	" "	No operation, after amputation through hip-joint.
5. E. W.	20	" "	No better; died 2 years after operation.
6. W. T. S.	34	" "	No better; died 1 year after operation.
7. M. T.	25	Tuberculous disease of metatarsus	Well and healed 2 years after operation; since then cannot be found.
8. N. O.	9	Tuberculous spine	Died 5 days after operation from intestinal obstruction.
9. E. B.	25	" "	Died of general tuberculosis 1 year after operation.
10. S. T.	18	" "	Left hospital much improved; lost sight of 3 months later and cannot be traced.
11. A. K.	11	" "	Died 2 years 3 months after operation from lardaceous disease.
12. J. H.	10	Multiple tuberculous foci in neck, limb s and back	No better 18 months later; cannot be traced.
13. W. C.	26	Tuberculous spine	Died from intestinal obstruction 8 days after operation of ilio-colostomy.
14. R. B.	23	Tuberculous spine	Died 2 years 6 months after operation from general sepsis; the local lesion was no better. Greatly improved. See note.
15. F. T.	20	Tuberculous spino	Died of general tuberculosis 5 years after operation; local lesion remained unhealed.
16. J. M.	9	Tuberculous hip	Died 19 days after operation from intestinal obstruction.
17. J. T.	12	Tuberculous gluteal bursitis	Unhealed a year later; cannot be traced.
18. L. B.	8	Multiple tuberculous glands	Died 4 years after operation of ilio-colostomy from septic absorption; local lesion remained.
19. A. P.	26	Tuberculous hip-joint	No better colostomy performed. Patient now greatly improved but not cured. See note.
20. J. H.	10	Multiple tuberculous—thigh, legs, neck glands	Died 1 year later; cause unknown.
21. J. H.	23	Tuberculous hip-joint	

Professor Rutherford Morison was most careful in his selection of cases, choosing those which seemed the most hopeless, and they all were examples of tuberculous lesions with superadded sepsis.

He performed the operation of ilio-colostomy on twenty-one patients during the years 1911, 1912, 1913. Of the twenty-one cases operated upon, three are known to be alive at the present time; one, a case of hip disease, is cured, while the remaining two are greatly improved, as will be seen from the notes printed below.

Five cases cannot be traced up to date; two of these were known to be well and healed two years after operation; the remaining three were not cured when last seen, eighteen months, twelve months, and three months respectively after the operation.

Three died from intestinal obstruction following the operation of ilio-colostomy, one on the fourth day, one on the eighth day, and one on the nineteenth day. In all three cases the diagnosis of intestinal obstruction was made early and they were operated upon at once, but the serious general condition of the patients interfered with recovery. Another case—a boy with a discharging left hip-joint—was no better as the result of the operation, and succumbed to amputation at the hip-joint thirteen months later. The remaining nine cases when traced were found to be dead as the result of tuberculosis either from the primary focus or from meningitis. They lived for periods varying from one to five years after the operation.

Cases Living at the Present Time.

CASE I.

T. H., aged 7, a feeble, anaemic boy, first came to the hospital in 1910 with a discharging tuberculous hip-joint. Operations to cure the local disease were performed in November, 1910, and again in 1911; during this time he was kept on the balcony of the ward in the open air.

In March, 1911, as there was no improvement in the local condition, ilio-colostomy was performed. When he left the hospital six weeks later the sinuses around the hip-joint were still open, but the discharge was diminished.

When seen again nine months after the operation the sinuses over the hip-joint were all healed, and he was greatly improved in health. A year later he commenced to work as a boot repairer, and now works regularly at this trade, earning £1 a week. In July, 1921, the following note was made: The local lesion shows a firmly healed scar over the left hip-joint, with many old healed sinuses and no active hip disease. The hip-joint itself has healed in the third stage of disease, and he wears a patten on the good foot and walks well.

To find out whether or not the large bowel was functioning after being short-circuited for so long a period as ten years he was given a meal of half an ounce of barium sulphate and examined with X rays. Five hours after the meal the salt was seen to be entirely in the small bowel in the region of the pelvis. Twenty-one hours after the meal the whole of the large intestine was seen to be filled with the salt and the small bowel to be empty. Two days after the meal barium was still present in the splenic flexure of the colon and rectum, the greater part having been evacuated; three days later no trace of the salt was visible. X rays, therefore, show that the short-circuited colon is still functioning after ten years.

CASE II.

A youth, aged 20, had caries of the spine at the age of 14. Six years before admission he had an abscess in the right femoral region, which was incised and drained. When admitted in 1913 he had a discharging sinus in the dorsal region, and another in the right thigh, which was also discharging freely. The dorsal spine showed marked kyphosis.

In February, 1913, ilio-colostomy was done. Eleven months later he looked much better, but the wounds were not healed. He stated that they did not heal until three years after the operation. This patient was not seen again until August, 1921, when he informed me that in 1918 he went back to work and worked at the pithead for one year, doing light work; an abscess then developed in his back and discharged freely. He stopped work, and in six months the wound was healed, and he has remained well.

A meal was given, and on X-ray examination six hours afterwards was found to be in the lower end of the small intestine. Twenty-four hours afterwards the salt was seen to be in the colon, reaching up to the splenic flexure. Thirty hours afterwards another X-ray examination showed the salt to be in the colon as far as the hepatic flexure, and in forty-eight hours in the splenic flexure and descending colon. In three days the bowel was empty with the exception of a small amount in the rectum.

In this case the barium was not actually seen in the ascending colon and caecum, but may have been there between the radiograms taken thirty and forty-eight hours after the meal.

the third case was not any better after ilio-colostomy, but complete colectomy was followed by improvement.

CASE III.

W., a sickly-looking and thin lad, presented himself with multiple tuberculous foci but with no bone lesion. He had abscesses in both legs, in the right hip, and in the neck. Numerous operations had been performed, and he still had abscesses when the ilio-colostomy was performed in 1913. He left hospital in due time, when his wounds showed some improvement. Two months later, however, he was readmitted with the foci charging as badly as ever; four months after ilio-colostomy was performed, as there was no improvement, Professor Morison took out the whole colon. The patient was lost sight of until 1921, when he was found to be greatly improved in condition, and although the wound was not healed he was able to do light work and sew canvas cover-sheets in the pursuance of his occupation. His wounds are now healed, but every now and then he has laid off work on account of sores breaking down over the knee-joint. He has fluid in the knee-joint, which, when tapped, was hot and showed active signs of inflammation. He states that his bowels are moved once daily with a solid motion, and that he has no diarrhoea.

I am indebted to Professor Rutherford Morison for his kindness in allowing me to publish these cases.

THE FUNCTION OF THE CHROMAPHIL TISSUES IN RELATION TO SPLANCHNIC STIMULATION.

BY

A. W. SHEEN, M.S., AND SWALE VINCENT, M.D.,
F.R.C.S., D.Sc.

(From the Physiological Laboratory, Middlesex Hospital Medical School.)

THE rise of blood pressure brought about by stimulation of the peripheral end of the splanchnic nerve is not simple, and the alterations (if any) produced in the curve by the elimination of the secretion of the chromaphil tissue of the adrenals from the circulation has not yet been precisely determined. The normal curve of splanchnic stimulation, according to several observers (1 to 3) consists of a rise on which is usually a "hump" followed by a marked "dip," and succeeded by a secondary rise prolonged as long as the stimulation lasts. Such a curve has been consistently obtained in dogs, cats, and rabbits.

When the adrenal secretion is eliminated, then, according to Pearlman and Vincent,⁴ in all these animals the "dip" is abolished, and the result of stimulation is a simple and prolonged rise. Gley and Quinquaud,² on the contrary, maintain that there is a difference between dogs and cats. They think that in the cat elimination of the adrenals makes no difference to the splanchnic stimulation curve, "dip" and secondary rise being maintained, while in the dog their results conform to those of Pearlman and Vincent, the "dip" and secondary rise being abolished.

The difference between these two sets of observers is fundamental, because the observations govern the interpretations of the curves. Gley and Quinquaud consider that the alteration of the curve in the dog is due to damage to some of the splanchnic vaso-constrictor fibres necessarily brought about while tying off the adrenals because of the anatomical conditions present, while in the cat the anatomy is such that the adrenals can be tied off without damaging the splanchnics and therefore the curve is unaltered—that is, withdrawal of adrenal secretion from functioning by way of the circulation has no effect on the curve.

Pearlman and Vincent, who found the "dip" abolished in all animals they investigated, naturally concluded that the alteration is due to withdrawal of adrenal secretion. There is no doubt that the anatomical connexions of the main splanchnic trunk and its associated ganglia with the adrenal body are more intimate in the dog than the cat. We have confirmed this by dissections. A drawing in Ellenberger and Baum's book⁶ shows well the condition in the dog. We consider, however, that while undoubtedly some nerve damage takes place in tying off the adrenals in the dog, it is not of such a character as to interfere with the main characteristics of the splanchnic curve. All observers are agreed that the main pressor effects persist. While in the cat the anatomical connexions are not so intimate certain nerves are undoubtedly damaged in it, as in all animals, in tying off the adrenals—namely, the nerves to the adrenal itself and the nerves to the kidney lying close behind the adrenal.

The majority of the experiments of Pearlman and Vincent were carried out on dogs. The present series has, therefore, been conducted on cats, with the simple object of ascertaining

whether the "dip" and secondary rise after adrenal elimination are abolished or maintained.

The animals were anaesthetized with ether or ethaneseal and anaesthesia maintained by intravenous injections of urethane. Blood pressure was taken from the carotid artery. After opening the abdomen the splanchnic—usually the left—was isolated between the diaphragm and the semilunar ganglion, divided where it left the muscular fibres of the diaphragm, and the peripheral length of nerve thus obtained—about 3 to 4 cm.—stimulated with various strengths of current. Prior to stimulation preparations were usually made for tying off the adrenals completely, or tying or clamping the adrenal veins, so that as short a time as possible should elapse between the stimuli. The anatomical conditions in the cat are such that the adrenals can be easily tied off without interfering with the main splanchnic connexions.

The results of these experiments show that by any method of adrenal elimination the normal curve is seriously altered. The "dip" is frequently abolished and is always considerably reduced. But a small "dip" sometimes persists after total elimination of the adrenals, and if this observation be true there is no escape from the conclusion that a part of the "dip" is due to factors other than the passage of a certain amount of adrenin into the circulating blood. Further investigations are required to determine completely the origin of the "dip," and we realize that one experiment where the "dip" is not entirely abolished is of more significance than any number where it is.

It should be added as confirmatory of adrenin effect that in two experiments the "dip" was practically abolished when the veins were clamped and subsequently restored to its full extent when the veins were released.

The "dip," in part at all events, is probably due to liberation of adrenin into the blood through vaso-constrictor impulses reaching the adrenals and causing them to contract, the small amount liberated having a vaso-dilator effect on the peripheral arterioles. This effect is quite temporary, the rise being again produced and maintained as long as the stimulation lasts.

SUMMARY.

1. Peripheral splanchnic stimulation in cats produces a characteristic curve in which an initial rise is followed by a marked "dip" and a prolonged secondary rise.
2. Elimination of the adrenals from the circulation abolishes or reduces the "dip," the more usual effect of splanchnic stimulation being a simple prolonged rise.
3. While the adrenal elimination is probably an important factor in altering the curve, further experiments are required to determine completely the origin of the "dip." Since some "dip" may occur after adrenal elimination, a part of the effect must be normally due to influences other than chromaphil secretion.

NOTE.—A portion of the expenses of this research were defrayed from the Scientific Grants Committee of the British Medical Association and the Government Grant Committee of the Royal Society to one of us (S. V.).

THE RELATION OF THE CORPUS LUTEUM TO MENSTRUATION AND PREGNANCY.

BY

W. R. MACKENZIE, L.R.C.S. EDIN.,
SURGEON TO THE SAMARITAN HOSPITAL, DELAWARE.

THE ovary, according to our present knowledge, performs a double function—the production of ripe ova and the elaboration of internal secretions, of which the chief is formed in the corpus luteum.

Fraenkel in 1903, experimenting on rabbits, formulated the theory that the corpus luteum regulates the blood supply of the uterus and thereby controls the process of menstruation and the implantation of the ovum in the uterus. I find that if this controlling influence be removed, either by excision or rupture of the corpus luteum, a woman will either menstruate

or abort depending upon whether a false or true corpus luteum has been injured.

Some very interesting observations have been made by American veterinary surgeons on cows. They found that if the false corpus luteum remained unabsorbed the cow did not come in heat (which corresponds with menstruation in women), but that if the corpus luteum was expressed manually the condition developed in a few days. I find that if during an abdominal operation the corpus luteum be excised the patient will have a period two or three days afterwards, even if she has only recovered from her previous period a few days before the operation. The following cases illustrate this:

CASE I.

Mrs. E., aged 29, married two years; menstruation was of the four weeks type. Bimanually there was a tender tumour to the right of the uterus which was normal in position when felt. Her last period terminated two days before operation. I found on opening the abdomen a right hydrosalpinx adherent to the ovary, which contained the false corpus luteum. In removing the tube the corpus luteum was resected. The patient menstruated forty hours after the operation.

CASE II.

Miss S., aged 25; menstruation of four weeks type, always regular; the uterus was retroverted and the ovaries prolapsed; her last period had occurred thirteen days before the operation. Ventro-suspension was performed and the corpus luteum excised from the ovary. The patient menstruated two days after the operation.

Another very interesting point is that the size of the corpus luteum has a distinct bearing on the amount of hæmorrhage lost at a period. On examining the ovaries during an operation, patients who have given a history of a heavy loss at their periods invariably have a large corpus luteum, and in those with only a slight loss the corpus luteum is small.

With regard to the true corpus luteum the veterinary surgeons made a very important discovery, that sometimes in expressing what they consider a false corpus luteum they have actually expressed or ruptured a true corpus luteum, in which case the cow has either aborted or bled to death. The following cases have a bearing on this observation:

CASE III.

Mrs. A. R., aged 28, married ten years, had had five children and one abortion; her last pregnancy was three years earlier. She was curetted at a hospital in October, 1919. She returned to this hospital during the first week of March, 1920; having missed two periods, she wished to know if she was pregnant. During the examination she felt a pain in her right side, became weak, and on going home went to bed. The next morning she noticed slight hæmorrhage, which she took to be her period returning. As it continued for two weeks she consulted her own doctor, who sent her to me at the Samaritan Hospital. I found slight tenderness in the right iliac fossa; bimanually the uterus was about the size of an orange, freely movable, with a soft, round, tender tumour in the right and posterior fornices. A pre-operative diagnosis of an extra-uterine gestation was made. The abdomen was opened by median subumbilical incision. The left ovary and both Fallopian tubes were normal, and lay above the fundus of the uterus. The right ovary was not seen. On exploring the pouch of Douglas I found a mass of old blood clot intimately connected with the right prolapsed ovary which contained a ruptured corpus luteum. This I removed. Not being satisfied that I had found the cause of the hæmorrhage I explored the uterus vaginally and removed a foetus.

CASE IV.

Mrs. McC., two months pregnant, was operated on for recurrent appendicitis. The apex of the appendix was adherent to the right Fallopian tube. In removing it I must, by handling the right ovary, have injured the corpus luteum, as the patient aborted next day.

CASE V.

Mrs. C., four months pregnant, had a subperitoneal fibroid about the size of a large orange, situated just below the right round ligament; it was removed without handling the ovaries. The patient made an uneventful recovery and went to term.

These observations throw very interesting light on the part played by the corpus luteum in abortion, sterility, premature menopause, and internal hæmorrhage simulating extra-uterine gestation.

During pregnancy, if a woman receives an injury to the abdomen, as, for instance, a fall or during bimanual examination (Case III), it is not the traumatism to the uterus which brings on the abortion, but rather that to the ovary, causing the corpus luteum to rupture; if rupture takes place through a blood vessel in the wall of the corpus luteum, intra-abdominal hæmorrhage occurs, showing all the physical signs of extrauterine gestation.

Frequent and often recurring abortions during the early months of married life are, I believe, brought on by injury, during coitus, to a corpus luteum contained in a prolapsed ovary.

In sterility, especially in elder women, why is it that after a course of pelvic massage they will become pregnant? Has a false corpus luteum been expressed? The same question arises with regard to the operation of dilatation for sterility. Is it possible that we unknowingly express a false corpus luteum when bimanually examining the patient, and by thus producing menstruation and its accompanying ovulation we prepare the way for conception, rather than by the dilatation and curetting of the uterus?

Conclusions.

I believe that the above data justify the following conclusions:

1. That injury to either a true or false corpus luteum will simulate a ruptured extrauterine gestation.
2. That injury to a true corpus luteum will bring on an abortion.
3. That rupture of a false corpus luteum will bring on menstruation and its accompanying ovulation.

MUCOCELE OF THE FRONTAL SINUS.

BY

J. ACOMB, M.B., B.S.,

ASSISTANT SURGEON, EAR, NOSE, AND THROAT DEPARTMENT,
COUNTY HOSPITAL, YORK.

THE notes of the following case may be of interest, first, because there seems to be strong reason to infer that the condition was due to trauma in early life, a cause which apparently is somewhat rare, and secondly, because it produced no more distress than that occasioned by occasional diplopia and a "pricking sensation in the right eye," as occurred in the case reported by Mr. J. A. Gibb (*BRITISH MEDICAL JOURNAL*, November 25th, 1921), and slight headache.

In January, 1917, Miss L., aged 28 years, consulted me on account of a small swelling at the inner and upper angle of the right orbit and of occasional diplopia. I thought the swelling was probably an osteoma. The first sign of anything wrong—the presence of the swelling—was noted about six months before she saw me. She took up war work as a masseuse, and three months before she came to me began to feel run down and to have headaches after a hard day's work or after reading, and at such times the diplopia troubled her more. She had seen an ophthalmic surgeon, who wrote to me that he considered the swelling was an osteoma or a fibrosarcoma. Immediately before seeing me she had consulted a surgeon who considered the condition to be due to nasal sinus disease. A skiagram was taken, which was negative in every respect.

On September 12th, 1921 (the description holds good for the first consultation in 1917), I made the following notes. Inspection showed slight proptosis of right eyeball with displacement downwards and outwards; neither of these features would have been noticeable on casual observation, the right pupil being about 3 mm. lower than the left. Across the bridge of the nose, which was broader than normal, was a linear oblique scar three-quarters of an inch long; it was the result of an accident when the patient was 3 years old which broke the nose and laid bare a considerable area of bone. A bilateral symmetrical bony boss could be felt on either supraorbital ridge about the position of the inner side of the supraorbital notch. The swelling complained of was below the boss on the right supraorbital ridge. Estimated by palpation it was about the size of an ordinary pea; it was bony hard, did not fluctuate, and was immovable but tender to deep pressure; there was no redness. The eyelids were freely movable; there was no lachrymation, and no history of nasal trouble, excepting that the patient thought the right nostril seemed narrower than the other. Headaches were confined to pain behind the right eye. Both fundi were normal; vision R. and L. = 6/6. In the diplopia the images were vertical without lateral displacement. Intranasal examination showed a deformed septum deviated to the right in the upper part and posteriorly. The nasal mucous membrane was apparently perfectly normal and healthy,

there was no discharge or history of discharge of any kind. The patient was seen with me by Dr. Macdonald, to whose help I am indebted; he agreed that the condition must be an osteoma.

Operation.

In September 30th, 1921, an incision was made along the right brow down to the periosteum. The supraorbital ridge was felt to terminate in a sharp irregular ridge, and in attempting to separate the orbital periosteum a thick gelatinous substance of a colour of very pale yolk of egg presented; this I swabbed and wiped away with a blunt spoon; it measured, perhaps, a table-spoonful. There was apparently a delicate envelope, and pieces of the floor of the frontal sinus adhered. After this removal the floor of the sinus remained. The cavity above was bounded by the roof of the sinus. Either there was no median septum between the right and left sinuses or it had been eroded; an opening which would have admitted a pencil led to the left sinus. The condition in the left sinus was obviously the same as the right, a further incision was made through the left eyebrow, the periosteum was reflected, and the floor of the sinus, which was thin and fragile, was chiselled through and the sinus emptied.

Both fronto-nasal ducts appeared to be occluded. Drainage was established by two thick gauze drains into the nose through openings made by a spoon in the position of both ducts. The incisions were sutured. The gauze drains were removed on the following day.

After-History.

A little blood-stained discharge continued to flow from the right nostril for some days.

Forty-eight hours after the operation I was called to the case, and in my absence Dr. Macdonald kindly saw the patient at about 10 p.m. He describes her condition as follows: "She was comatose, curled up in bed; could not be roused. Temperature 102°. Did not respond to any stimulus. Reflexes normal." By midnight her condition was improved in that she could be got to respond to vigorous stimulation, but in the circumstances the condition was probably the onset of meningitis. On careful examination came to the conclusion there were conditions being at least partly relieved.

AMOEBC LIVER ABSCESS. THE FOLLOWING DAY SHE WAS PROBABLY SO IMPROVED BY IMMEDIATE AND UNINTERRUPTED IMPROVEMENT.

The following day she was so much improved as to be able to say her head ached. The temperature reached 100° in the evening, but from this date she rapidly got well, and three weeks after operation only complained of a little occipital headache and occasional diplopia after a quarter of an hour or so of reading or close work. The wounds healed with practically no disfigurement.

The gelatinous substance and lining was examined by the hospital pathologist. His report was as follows:

"I find the fluid contains no cells and is of a mucoid nature, whilst sections of the solid pieces show them to be the normal mucous lining of the tissues. These results lead me to think that the condition was probably due to accumulation of the normal secretion."

The Kettisomian Lectures

ON

AMOEBC LIVER ABSCESS.

DELIVERED BEFORE THE MEDICAL SOCIETY OF LONDON.

BY

SIR LEONARD ROGERS, C.I.E., M.D., F.R.S.

[Abstract.]

LECTURE III.—THE PREVENTION OF AMOEBC LIVER ABSCESS AND THE RECENT REDUCTION IN THE PREVALENCE AND MORTALITY.

In his final lecture Sir Leonard Rogers said that from what he had so far indicated with regard to the pathology and treatment of amoebic liver abscess, it would be sufficiently obvious that any simple method of preventing such a complication would be far more beneficial than even the most certain and established methods of cure. He wished, therefore, to devote himself in this third lecture to the measures which had enabled him to establish such prevention on a scientific basis. Ipecacuanha appeared to have been used at quite an early date in India in dysentery and hepatitis, but afterwards was superseded. In 1855, however, ipecacuanha was being used in large doses for dysentery among the British troops at Mauritius, and there were records of its reintroduction at a still earlier date. Maclean in 1854, in writing on hepatitis, did not mention ipecacuanha, but advised saline purges, strict dieting, and the cutting off of alcohol. In the same author's article in Reynolds's *System of Medicine* in 1871, however, he stated that for years past he had advised 20- to 25-grain doses of ipecacuanha in acute hepatitis, and remarked upon it

as a curious fact in the history of tropical medicine that in dysentery this drug should have been superseded by calomel and opium. It was now clear that such violent fluctuations in treatment were inevitable in India so long as amoebic dysentery remained undistinguished. Sir Patrick Manson had consistently advised large doses of ipecacuanha whenever hepatitis was associated with dysentery, and long before he recognized amoebic dysentery as a distinct disease he recommended ipecacuanha in cases invalided home from the tropics.

Blood Changes in the Early Recognition of Amoebic Hepatitis.

The lecturer continued his description of the researches which led up to the differentiation of the presuppurative stages of amoebic hepatitis, with prevention of abscess formation, rendering surgical interference unnecessary. Coincidentally with his studies in the etiology of amoebic liver disease he was working on blood changes in fever admissions. At the time he began this work (1901) it might safely be said that 90 per cent. of the fever cases were diagnosed and treated as malaria, although he found that only one seventh of them were really so, and among the fevers at that time nearly always confused with malaria were the more chronic forms of amoebic hepatitis, which were always treated with quinine. It was known that amoebic hepatitis produced a leucocytosis, but with no pathologist and a very small staff of overworked clinicians there was no detailed history of blood counts until he began his own investigations in Calcutta.

From his notes collected at that time he found that during nearly four years none of the hepatitis cases (including those going on to abscess formation) had been treated with ipecacuanha. It was clear, therefore, that at this time, in Calcutta at all events, the specific drug had been superseded by ammonium chloride in hepatitis. He showed some tables of cases to illustrate the leucocytosis which was found.

In a first series of five cases admitted for hepatitis and not going on to suppuration only two showed a very slight increase in the leucocytes. In sixteen other cases which went on to liver abscess all except one showed a leucocytosis, and even in that one there was a relative increase in leucocytes. The counts were: there was leucocytosis varied from 12,750 to 33,500 leucocytes. The case which showed 33,500 leucocytes and another which showed 35,000 were cases of multiple small liver abscesses which rapidly proved fatal. In the more chronic and insidious forms leucocytosis was absent on admission, but developed later under ammonium chloride treatment.

At this stage in his investigation he had already proved that tropical liver abscess always contained amoebae, but rarely pathogenic bacteria. Therefore the abscesses were almost certainly caused by the amoebae, and were preceded by amoebic ulceration of the colon. He became convinced that ipecacuanha was a specific for the amoebic variety of dysentery, although useless for the bacillary form common in Indian galls. Although cases in this presuppurative stage might or might not give a history of previous dysentery, he knew from his experience of the leucocytosis that latent amoebic ulcers must be present in some part of the large bowel which were healed by large doses of ipecacuanha.

Ipecacuanha in the Prevention of Amoebic Abscesses.

It was not, however, until 1907 that he was able to record a convincing series of successful cases. This included 15 cases of hepatitis he had met with among 1,350 consecutive fever admissions, or just over 1 per cent. It was not surprising that cases occurring in so small a proportion of the total number had not been differentiated by busy clinicians in the absence of blood examination.

The first three cases, which he showed in tabulated form, were cases of dysentery and hepatitis treated with ipecacuanha. The blood showed leucocytosis in all three. They had suffered from fever for eighteen, thirty-four, and forty-one days before they were put on ipecacuanha, and the fever ceased two, four, and three days after the full dose of this drug. The next eight cases were cases of hepatitis without dysentery: there was no previous history of dysentery, nor was there dysentery while in hospital, but one or two of them showed diarrhoea, and others constipation, and so on. In three of these cases, which were treated only with ammonium chloride, the fever went on for thirty-four, forty-four, and forty-nine days before the temperature came down. The others were treated with ipecacuanha, and the temperature quickly fell. Another group of four cases were cases without either dysentery or obvious liver symptoms; they were obscure cases of fever. Two of them showed leucocytosis on admission, and the other two developed it later, and on the strength of this all of them were put on ipecacuanha, and the temperatures came down quickly, in one case within two days.

The lecturer showed temperature charts obtained in these various cases. In one case the fever had lasted fifty-eight days

before the ipecacuanha was given, yet after it was given the temperature came down in two days. Taking the whole of this series, it was noteworthy that 12 out of 15 cases were unassociated with dysentery, yet he was able to recognize them as amoebic in origin, and treat them with ipecacuanha. Of 21 other cases admitted with hepatitis and treated with quinine and ammonium chloride, 16 went on to suppuration, while of 12 cases treated with ipecacuanha, 11 of them showing well-marked leucocytosis, every one rapidly cleared up without going on to suppuration. There could be no doubt, therefore, that suppuration was averted by the use of ipecacuanha. When one got a very high leucocyte count in such a case as multiple liver abscess the polynuclear percentages were usually between 80 and 90, and the total leucocytes might range above 30,000, which carried a very serious prognosis. But he had seen a case of severe hepatitis, with a count of 20,000 or 25,000, cured by ipecacuanha without going on to suppuration.

Chronic Amoebic Hepatitis as a Common Cause of Cirrhosis of Liver in the Tropics.

The lecturer then turned to consider chronic amoebic hepatitis as a common cause of cirrhosis of the liver in the tropics. In an analysis which he had made of the records of nearly 5,000 *post-mortem* examinations in Calcutta, extending over a period of thirty-seven years, he found 6.9 per cent. of cases of well-marked cirrhosis of the liver. As this disease was common among Mohammedans, who were prohibited by their religion from taking alcohol, some other cause than alcoholism had to be looked for. On working out the percentages of the principal complications, he found granular kidney in 28 per cent. of the fatal cirrhosis cases and 13 per cent. of the latent cases, and dysentery in 25.6 per cent. of the fatal cases and 30.1 per cent. of the latent cases. Further investigation confirmed the intimate relationship between cirrhosis and dysentery, but the question remained as to the form of dysentery to which these cirrhosis cases related. Fortunately, he was able to complement his study of the *post-mortem* records by eight years of actual experience of necropsies in Calcutta, and he could testify that he found evidence of former chronic amoebic dysentery in three-fourths of the cirrhosis of liver cases; it was always of the amoebic variety. It was not difficult to account for the close relationship between these two diseases; he ascribed the cirrhosis to the long-continued amoebic irritation of the portal branches in amoebic dysentery, leading eventually to increased interlobular fibrous tissue.

Was there such an entity as "tropical liver" apart from amoebic hepatitis? The latest edition of Sir Patrick Manson's book introduced a graphic description of tropical liver, but the lecturer himself believed that the survival of the term "tropical liver" from the writings of nearly a century ago was fraught with danger. It was very interesting to note that such a warm advocate of ipecacuanha as Norman Chevers had said that he knew nothing of the mysterious disease called tropical liver. The abuse of alcohol doubtless did affect the liver in the tropics as elsewhere, while the remarkable immunity of women and children to liver abscess might be explained by their non-addiction to alcohol, though he thought there were other factors. But he urged that the so-called "tropical liver" should never be put on ammonium chloride treatment until amoebic disease had been definitely excluded.

He related the case of a patient admitted for dysentery which subsided in ten days after a castor-oil mixture had been given; but seven days later the patient developed an acute hepatitis, with high fever, pain in the right shoulder, and a slight shadow in the liver as seen under x rays. The surgeon diagnosed abscess, and was only persuaded by the lecturer to give ipecacuanha treatment before proceeding to operation, owing to the fact that the man had had dysentery before. Within two days after the administration of the ipecacuanha the pain ceased, within three more the temperature fell to normal, all signs of liver abscess disappeared, and there was a complete recovery without recourse to operation.

The Decline in Incidence of Amoebic Disease.

If all that had been claimed with regard to the prevention and treatment of liver abscess was true, some results ought by this time to be reflected in the statistics of cases, taking a wide area and a considerable period of years. Several years ago he published certain figures relating to the liver abscess cases occurring at the European General Hospital at Calcutta during the five years previous to his reintroduction of the ipecacuanha treatment and during the six years following. He had now brought the figures up to date (1921), and they showed a reduction of nearly one-half in the annual admissions during the later period as compared with the former, and the mortality from 43.5 to 23.3 per cent. He also gave figures for hepatitis and liver abscess cases at the

London School of Tropical Medicine during the period before the use of ipecacuanha was established as a means of preventing suppuration, during the period after ipecacuanha, but before emetine treatment was established, and during the period for which both treatments had been in vogue. In the first period the number of cures of liver abscess was 5 out of 13 cases, in the second 10 out of 15 cases, and in the third the whole of the 14 cases admitted had been cured.

The most convincing demonstration, however, was afforded by a chart which he had carefully plotted to show the incidence of amoebic hepatitis and liver abscess, and their relationship to dysentery and diarrhoea, in the British army in India during the last fifty years. The number of British soldiers in India during this period varied from 50,000 to 80,000. The incidence of hepatitis during the fifty years from 1869 onwards showed a steady fall. Dysentery showed a general decline broken by a number of epidemic rises, and diarrhoea showed the same features, the epidemic peaks occurring in the same years as in dysentery. When there was an epidemic rise in dysentery, the ratio of liver abscess to dysentery fell, thereby suggesting that the great majority of cases of epidemic dysentery were not that form of dysentery which was related to amoebic liver abscess and hepatitis—that is to say, not the amoebic form but the bacillary form; and it was known that the bacillary form was the one which gave rise to these epidemics. The close relationship between diarrhoea and dysentery which the chart demonstrated was of great importance. Diarrhoea was just as closely related to hepatitis as dysentery. There were two cases of hepatitis to every three cases of dysentery, and also to every three cases of diarrhoea. The correlation was extraordinarily close. A large number of cases of diarrhoea in India were really cases of amoebic disease, and would be better called amoebic colitis, for the grouping of them as diarrhoea rendered them liable not to be treated with ipecacuanha, and accordingly many of them went on to amoebic abscess. Another important fact in this connexion was that in an analysis of 1,000 *post-mortem* examinations, correlated with clinical findings, 50 per cent. of the fatal amoebic dysenteries were found not to have been recognized as dysentery at all in hospital; the diagnosis was almost invariably chronic or tuberculous diarrhoea, so that many fatal dysentery cases only gave rise to the symptoms of diarrhoea, and a large number might have been readily cleared up with ipecacuanha. In the earlier period to which the chart related there was a decline in the case-incidence of amoebic abscess, but a less marked decline in the mortality, and this, the lecturer suggested, was due to the fact that open operation about this time came into general favour and aspiration was relegated to the background. The decline in liver abscess went parallel with the somewhat similar course of hepatitis. Between 1896 and 1902 there was a rise in the number of cases of liver abscess, the high level continuing until about 1907, and the incidence of hepatitis meanwhile fell at first and afterwards remained practically stationary, so that there appeared to be nothing to account for this extraordinary rise in liver abscess. The maximum year for liver abscess cases was 1902, and this was the time when, immediately after the Boer war, a large number of army medical officers returned to India from South Africa, where they had had to deal almost entirely with the bacillary form of dysentery, and had found saline treatment of great value. Even previous to this the saline treatment had been boomed in India, owing to the successful use of it in gaol dysentery, which was of the bacillary type. The marked rise in the prevalence of liver abscess in the British army at that time was obviously due to the neglect of ipecacuanha in favour of the then popular saline treatment. The ratio of liver abscess cases to dysentery suggested the same conclusion; during this rise in the prevalence of liver abscess the ratio of liver abscess cases to dysentery was doubled.

The latest period of this inquiry, from about 1907 onwards, showed, as regards liver abscess, a rapid fall until the frequency of cases was diminished to less than one-third of what it had been in the early period, and there was also a marked fall in the death rate. During this same period both dysentery and diarrhoea rose for a time to double their ordinary numbers, but the incidence of liver abscess still remained very low, and the death rate reached the lowest point of all. It was still more remarkable that the curve representing hepatitis actually fell to its lowest point at the very time when dysentery and diarrhoea were rising. The year 1907, which was the last year of high incidence of liver abscess, was the year in which he demonstrated the great

value of ipecacuanha in preventing abscess formation. The fall in the mortality had begun a year earlier, and this coincided with the adoption of the treatment by aspiration and injection of amoeba-destroying drugs. Altogether the death rate in cases of liver abscess declined from 56 per cent. in the earlier period covered by the chart down to 28 per cent. in the end period. He concluded that the great reduction both in the prevalence and the mortality of liver abscess was due to preventive measures by means of ipecacuanha and to treatment by the aspiration and injection method. The decline in hepatitis as related to dysentery was also marked after the establishment of emetine treatment.

The Medical Cure of Multiple Small Amoebic Liver Abscesses.

The final question to which the lecturer addressed himself was the possibility of cure by medical means alone of already formed amoebic liver abscess. He had long thought that such cure was possible, and he now felt assured that this could take place under emetine treatment. He thought also that the small early acute multiple liver abscesses should prove very amenable to the specific action of ipecacuanha and emetine. It was wonderful what emetine treatment of a week's duration could do in the way of removing the extensive gelatinous infiltration characteristic of this condition. Emetine was probably the most definite specific drug known to medicine. Some day it would gain a place in the *British Pharmacopoeia*, even if some hoary remedy had to be sacrificed to make room for it.

In concluding his series of lectures, Sir Leonard Rogers referred to the foundation in Calcutta of a post-graduate research school of tropical medicine. He had long been convinced that, in the absence of post-graduate teaching, a new generation of medical men must arise before the general public could reap the benefit of the conclusions of the research worker. In the particular province with which he had had to deal in these lectures, he could say that amoebic disease was easily preventable in the great majority of cases, and that the development of amoebic saparation in the liver should cause serious questioning to arise in the mind of the medical man in whose hands it had occurred; while in the case of patients who came under observation with an already formed liver abscess the treatment of election should be aspiration and emetine, with some form of sterile siphon drainage if necessary. He was convinced that with the more general adoption of the measures for which he had pleaded, whose rationale he had established as the result of careful observation extending over many years, this particular tropical disease might be almost completely abolished, thereby rendering tropical and subtropical countries safer and easing the white man's burden.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

EXOPHTHALMIC GOITRE IN CONGENITAL SYPHILIS.

CONGENITAL syphilitic affections of the endocrine glands are of much interest, and so I venture to think that the following case of exophthalmic goitre in a child suffering from congenital syphilis is worth recording. The adrenals, pituitary gland, and the testes are said to be the endocrine glands most often structurally damaged in congenital syphilis, and affections of the thyroid are rare, especially myxoedema and exophthalmic goitre, although hypothyroidism is not so uncommon.¹

The patient is a fairly well nourished girl, aged 4½ months. The mother states that the child has abscesses of the buttocks. The mother had one child in 1914, which is stated to be quite well. In 1917 the mother was found to be suffering from late secondary syphilis, and her Wassermann reaction was positive. She received galyol 0.25 gram intramuscularly, kharsivan 2.1 grams intravenously, and 7 grams of mercury intramuscularly. She then discontinued treatment. She states that in 1915 she had a stillbirth at full time.

Present Condition of the Patient.—The weight of the child is 11½ lb. Both lobes of the thyroid are enlarged. This is very noticeable when the child draws its head backwards or cries. The eyes are prominent, and show the "thyroid stare." Von Graefe's sign is present, Mobius's sign absent. The heart is apparently normal; the pulse rate before examination is 134, after examination of the child, 160. There are no nervous symptoms. A few papulo-

squamous spots are present on the face, several pustules on the trunk. Saddle-nose is present. On the right buttock is an undetermined ulcer, on the left buttock one pustule. The glands, mouth, pharynx, tongue, are all apparently normal. The Wassermann reaction is positive.

NOEL F. ROWSTON, M.D.,
Honorary Physician, Skin Department, Royal
Infirmary, Sunderland.

PNEUMOCOCCAL PERITONITIS SIMULATING ACUTE GANGRENOUS APPENDICITIS.

It has been my unfortunate experience during some years of practice to come across several cases of pneumococcal peritonitis in which the diagnosis of acute appendicitis was made and an operation for its removal undertaken. In all cases similar conditions were noticed. The abdomen was filled with pus, like thin cream, with a faint yellow-green colour, but without faecal smell. The appendix was easily found—ejected externally, but healthy internally. The bowels had the same appearance.

To all intents and purposes, at the operation these cases are looked upon as a favourable variety, but if only the precaution of rapidly making a blood count, before deciding upon operation, were taken it would be found that most of these cases have a leucocyte count of over 30,000 per cubic millimetre, some 45,000 per cubic millimetre. The gravest prognosis must be given; all the cases I have seen have died within four days after the operation.

The previous symptoms in these cases, as seen in children from 3 to 12 years of age, are interesting, for the patients rarely complain of abdominal pain; the abdomen is quite supple, and there is no rigidity in the appendix region, nor of the lumbar muscles. The abdomen does not move with the respirations.

Acute appendicitis due to the streptococcus must not be confounded with these cases, for here we usually have the classical appendix symptoms and an acutely inflamed appendix with thin serum. The prognosis depends upon the blood count, and if it is 30,000 leucocytes per cubic millimetre or over, one may safely say that the case is hopeless; the fact that we now have many antistreptococcal serums to use may alter the outlook in an otherwise desperate condition, if heroically administered. The usual favourable acute appendicitis has, as a rule, a blood count of 14,000 to 20,000 leucocytes per cubic millimetre.

Bognor.

J. F. REY.

INTESTINAL OBSTRUCTION DUE TO PARALYTIC ILEUS.

A. B., a woman aged 55, was under the care of my partner, Dr. T. Murray Newton, and myself for five months suffering from vomiting. This occurred two or three times during the day, it had no relation to meals and no distinctive features. She had no pain; the pulse and temperature were normal, and the tongue was clean. She was thin and very sallow. The examination of the abdomen was negative. Constipation was a salient symptom throughout, and aperients were continually required. Dieting and rest in bed for two months relieved her condition so that she was able to go about. She, however, vomited occasionally, and retained a very sallow colour. Generally she had lost weight.

During August her condition became much worse. On the 25th there was very frequent vomiting, a rising pulse rate, and the abdomen was slightly distended. The next morning the vomiting had become continuous, the abdominal distension was much more marked, and there was very marked peristalsis. Dr. Denyer, physician to Hull Royal Infirmary, agreed that she had intestinal obstruction, and that immediate operation was necessary.

I opened the abdomen the same evening, and found all the colon immensely distended, but there was no obstruction in the rectum nor any part of the colon. Examination for other causes proved negative. The central incision was closed and a temporary colostomy made. The vomiting stopped immediately, and she has never vomited since. Full-sized motions were passed by the rectum after the fifth day, and some faeces through the colostomy. The sallow colour has disappeared. She has obviously in better health than she was, which at operation was 55 years. The weight, which at operation was 55 lb., is now 65 lb. on February 18th.

The case seems to fall into the atony following stasis and haeter in Nothnagel's *Encyclopaedia*.

Reports of Societies.

FACTORS IN THE CAUSATION OF PUERPERAL SEPTICAEMIA.

A MEETING of the Section of Epidemiology of the Royal Society of Medicine was held on February 24th, under the presidency of Dr. A. K. CHALMERS, when a paper was read on the relation between puerperal septicaemia and other infectious diseases, including a reference to the propriety or otherwise of admitting maternity cases into isolation hospitals.

Dr. EVELYN D. BROWN, the author of the paper, confined herself to certain conclusions at which she has arrived as a result of an extensive study of statistics, including the Registrar-General's returns, the notifications of infectious diseases, and so forth; but very few figures were given in the paper itself, although, in view of the importance of one at least of her conclusions, it would have been useful to have had exact figures and to have known the precise area covered by the analyses.

At the outset Dr. Brown referred to the long-standing controversy with regard to a possible connexion between puerperal fever and liability to scarlet fever infection. When discussion on this subject first arose many years ago the chief interest lay in its clinical aspect; but to-day, when municipal authorities had to deal with the provision of accommodation for maternity cases, the question had its importance also on the administrative side. Some distinguished obstetricians of a generation ago held that scarlet fever arose as a complication of childbirth even when no exposure to infection had taken place, so that liability to scarlet fever was not a condition superimposed upon the puerperal state but was a part of that state. The whole question was complicated by the variations in the clinical picture of scarlet fever in different periods of years. There was good reason to believe that the prevalence of scarlet fever was fairly constant from year to year, but the discomfort which it caused varied greatly in intensity, and it was according to the discomfort that the condition was assessed. Her analyses of statistics over a considerable period of years led her to the conclusion that there was no association between the rise and fall of puerperal septicaemia and of scarlet fever, such as would have been expected on the old theory; and, indeed, that there was no parallelism between the incidence of puerperal septicaemia and that of other infectious diseases, such as diphtheria and influenza, with the possible exception of measles, where there was a significant positive correlation.

During the last fifty years the puerperal mortality rate had altered very little, although there had been a marked fall in the birth rate and in the death rate from all causes. What was it, then, that maintained so steady a death rate from sepsis following childbirth? Was there an inherent, unalterable factor in the patient herself, beyond the control of preventive or curative measures? Such an argument must be the last defence of the perplexed. All the evidence went to show that sepsis was not dependent upon the strain of repeated child-bearing, nor upon intrinsic factors, such as the age of the mother. Tables had been drawn up from the records of midwives in large practices, in districts of varying social character, which showed that there was a tendency for the occurrence of abnormality in the earlier age groups rather than in the later, and abnormalities were likely to be associated with temperatures. This seemed to dispose of the suggestion that the slightly later age of marriage now prevailing was responsible for keeping up the puerperal mortality, for the effect of a later age of marriage would be to place an increased number of births in the later age periods, in which the puerperal mortality rate was rather less. Nor was there anything to suggest that the woman with domestic advantages was either more or less liable to septic infection during childbirth than the working woman. It was therefore to external causes that attention must be turned to explain the failure to obtain any significant reduction in the rate of septic mortality. Here Dr. Brown ventured the conclusion from her correlations between the number of doctors per 1,000 of the population and the mortality rates from puerperal fever that the practitioner, rather than the midwife, might be the carrier of sepsis to the parturient woman. The statistics—into which she did not enter—suggested the doctor as a factor in the transference of infected material, and a little thought concerning the calls made upon the busy practitioner and the conditions under which he had

to work might suggest the *modus operandi*. She believed that puerperal septicaemia was a preventable disease, that its prevalence was determined, not by the organisms of scarlet fever, diphtheria, or influenza, but by the organisms of erysipelas or septic cutaneous lesions, and that in consequence, given efficient administration, it was a safe and practical policy to admit maternity cases to isolation hospitals.

Dr. REGINALD DUDFIELD contested Dr. Brown's deduction with regard to the doctor as a source of infection. His own figures, so far as they went, established a lower prevalence of puerperal fever among cases attended by doctors than among those attended by midwives. He also reminded the Section that a very large proportion of the cases in which a doctor was called in were complicated labours in which puerperal fever was liable to occur, and it did not seem fair to debit the doctor with these.

Dr. R. J. EWART said that serious complications had been remarkably few among the 300 or 400 maternity cases admitted into the isolation hospital at Barking, and there had been only one death from puerperal sepsis following instrumental delivery. The maternity ward was about 40 ft. away from the diphtheria ward, and the latter had been overcrowded, but, although the two nursing staffs continually crossed one another's path, no case of diphtheria had occurred in the maternity ward. He believed that in studying the prevalence of infectious diseases they were apt to concentrate too much upon mere discomfort, and that as a matter of fact scarlet fever and diphtheria in a form which went clinically unrecognized were very common, so that by the time adult life was reached many women had become immune to these infections, and the only infection to be feared in childbirth was a surgical one.

Dr. MAJOR GREENWOOD referred to the views held by medical men half a century ago and longer as to the relation between scarlet fever and puerperal septicaemia; he thought these views were largely coloured by the fact that of all the zymotic diseases—small-pox being then on the down grade—scarlet fever was the one which produced the greatest mortality among grown-up persons, and the association of this condition with puerperal septicaemia might, therefore, be mainly psychological. He added that although Dr. Brown had followed the right line of investigation, it was not sufficient to work out sets of coefficients of correlation on one year's records, for misleading correlations might easily be forthcoming when the ratio with which one was dealing depended upon very small absolute numbers, so that not too much was to be inferred from correlations when the observations were not repeated over several years.

Dr. REMINGTON HOBBS said that the cause of the rise in temperature in the parturient woman was some mechanical blocking of the genital tract. If the natural secretions were pent up, the organisms would ascend. He believed that latent infection was present before childbirth, that the organisms were carried through the later months of pregnancy, and asserted themselves when there was opportunity. The temperature was brought down by a proper system of drainage.

Among other speakers were Dr. W. H. HAMER, who could not help feeling still that there was some kind of relation between scarlet fever and puerperal septicaemia; Dr. ELIZABETH MACRORY, who urged that doctors should carry out their personal disinfection on attending maternity cases with the same scrupulous care as the good midwife; Dr. E. W. GOODALL, who believed that the idea that women in the puerperal state were likely to get scarlet fever arose from erroneous observations, and also added that he had seen many women come into hospital with scarlet fever and be confined in hospital without getting puerperal fever; and Dr. J. C. McVAIL, who thought that Dr. Brown had suggested a case for a very serious inquiry on a large statistical scale—the matter was certainly one which should be pursued.

NITROUS OXIDE ANAESTHESIA.

At a meeting of the Section of Anaesthetics of the Royal Society of Medicine on February 3rd, with Dr. H. J. SHIRLEY, President, in the chair, Dr. A. L. FLEMING opened a discussion on the utility and limitations of nitrous oxide anaesthesia. It would, he said, only court disaster to ignore the difficulties associated with the administration of gas or to minimize its possible dangers. In former years the choice of anaesthetic most often lay between chloroform and ether; now it was

generally between ether and gas oxygen. Although experienced administrators could use gas and oxygen for almost any type of patient or operation, yet, whereas ether could succeed none, the gases required in many instances the aid of preliminary injections, of local anaesthetics, or of ether. Certain physiological and pharmacological properties of nitrous oxide must be borne in mind. It had been shown that nitrous oxide exerted a specific effect upon the nervous tissues, that the motor areas remained more sensitive during the anaesthesia of gas than during that of ether, that gas somewhat abruptly interfered with oxidation of the tissues, that animals were killed by gas more quickly than by asphyxia, and that in animals the red blood corpuscles were diminished 25 per cent. after thirty minutes' anaesthesia with nitrous oxide. Nitrous oxide was a powerful drug but a poor relaxant. Consequently dosage was of importance, and to procure relaxation without cyanosis the addition of oxygen instead of air was necessary. In former days prolonged administrations of gas and air had been attended by dangerous respiratory depression and by outward displacement of the heart's apex. If enough ether was used with gas and air a very satisfactory result might be obtained. Nitrous oxide and oxygen alone might give rise to dangerous respiratory and circulatory embarrassment in the presence of abnormally high or low blood pressure. The anaesthesia might be followed by troublesome nausea. Nitrous oxide was most safe when used, not as the main or sole relaxant, but in conjunction with other agents. Dr. Flemming related cases illustrating difficulties that might be encountered during the use of nitrous oxide, oxygen, and ether, and discussed the efficacy of the two anaesthetics in combating or preventing shock.

Dr. G. A. H. BARTON protested against the loose use of the term "gas and oxygen" for a method which often involved the use of ether. If the anaesthetist confined himself to nitrous oxide and oxygen he met with many unsuccessful cases. If he first got the patient under with gas and ether and then continued with nitrous oxide and oxygen many good results were obtained. Often the best method was to give small amounts of ether throughout, along with the gas and oxygen. The method had advantages, if used intratracheally, in most operations about the head and neck and on the limbs. For throat operations he considered the anaesthesia insufficient, and the same was true of abdominal operations. The subjects of diabetes, albuminuria, and respiratory catarrh were especially well suited to gas and oxygen. For shock he could not agree with the value placed upon the method.

Mr. H. E. G. BOYLE remarked that the proper administration of nitrous oxide and oxygen and ether requires skill and constant practice. For the average man giving only occasional anaesthetics ether should remain the anaesthetic of choice. He believed in making induction of unconsciousness as quick as possible. He used ether or CE in conjunction with the gases as necessary, but it was remarkable how small an amount of these additions was needed even in long cases. Mr. Boyle believed that shock was less after the gases than after ether or chloroform. McKesson's secondary saturation certainly produced relaxation without any additional anaesthetic to nitrous oxide, but Mr. Boyle was not disposed to imitate the method.

Mr. J. H. CHALMERCOTT said that the only method of using gas and oxygen which produced ideal results in abdominal and other serious operations was that of combining it with local anaesthesia. Satisfactory relaxation during operation and a minimum of discomfort afterwards could be obtained in this way only. The nerve blocking provided the relaxation and the freedom from shock. The nitrous oxide was responsible merely for unconsciousness. He deprecated the use of nitrous oxide and oxygen alone for these cases, but for other operations it was a good plan to induce anaesthesia with gas and ether and continue with gas and oxygen. For desperate cases he would not employ gas and oxygen except with nerve blocking. If the latter were not employed he would prefer ether.

Mr. H. M. PAGE said that after much experience he would be very sorry to abandon the water-feed apparatus for gas and oxygen. Several years ago he had advocated the induction of anaesthesia by gas and ether and its continuance with gas and oxygen. When difficulties occurred they should be met by recourse to additional ether, not by pushing the nitrous oxide; yet every saving of ether vapour that could be effected by the use of gas improved the after-state of the patient.

Dr. F. E. SHIPWAY regretted the absence of a physiologist who could explain to them the causation of alarming symptoms that arose under gas and oxygen. Some cases of sudden and unexpected fatality during the inhalation were explained by the writings of Haldane, who had shown that acute or long-continued anoxaemia more quickly and certainly paralysed the respiratory centre than it did the heart. Slight changes of colour were difficult to detect, and clinically some oxygen deprivation might be produced unawares. In handling difficult subjects Dr. Shipway recommended increasing the oxygen supply and addition of ether rather than reliance on nitrous oxide. The latter was contraindicated, particularly in persons of high blood pressure or with arterio-sclerosis. Nor was gas and oxygen suited to active or recently healed tuberculous lungs. The rapid or deep breathing which might be set up was prone to cause spread of the disease or fresh breaking down. Gas and oxygen was the best anaesthetic in the treatment or prevention of shock, and Dale's work on histamine was most suggestive in this connexion.

DIAGNOSIS AND TREATMENT OF ACUTE TUBAL PERITONITIS.

At a meeting of the Edinburgh Obstetrical Society held on February 8th, with the President, Dr. LAMOND LACKIE, in the chair, Mr. J. W. STUARTS read a communication on the diagnosis and treatment of acute tubal peritonitis.

Cases of tubal peritonitis, he said, might be roughly divided into two groups: those due to leakage from established chronic infective lesions of the uterine appendages, and those due to the spread of a recent tubal infection to the peritoneum. In both groups the onset of pain in the lower abdomen with vomiting and fever signalized the peritoneal involvement. The pain was usually bilateral, but was often more severe on one side than the other, and tenderness and muscular resistance corresponding to the pain were present. If the symptoms were definitely limited to the right iliac region, and if there was no history of pelvic disease or vaginal discharge, a tubal infection might be ruled out; but when the pain and tenderness were more central or bilateral the presence of tubal infection must be excluded, though a history of previous pelvic trouble would naturally direct suspicion towards the tubes. Examination under anaesthesia was usually advisable, and if diseased tubes were felt the question then arose as to whether operation should be carried out at once, or whether the acute stage of the illness should be allowed to pass and operation undertaken later. Operation was rarely needed to save life, as the infection was seldom of a virulent type. On the other hand, removal of the diseased tubes entailed the illness, prevented recurrence, and, if there was no possibility of restoration of function occurring, did not prejudice the patient in any way. If, however, conditions for operation were unfavourable, delay involved no serious risk provided we could be sure that the diagnosis of pyosalpinx could be confidently made, and that the symptoms were not those of a virulent infection. The difficulty arose in cases where salpingitis could not with confidence be diagnosed from appendicitis. Vaginal discharge was often very slight, and pelvic examination gave no help, for the tubes were not sufficiently enlarged to be recognized as diseased, while an inflamed appendix lying in the pelvis might give rise to similar clinical features. If the abdomen was opened and the tubes found to be diseased, should they be removed in every case; or if the infection appeared to be a mild one should they be left in the hope that function might be restored and pregnancy ensue? It always seemed to him a difficult matter to leave tubes *in situ* from which pus was actually leaking. If, however, it could be shown that in a definite number of cases resolution and restoration of function of the tubes might follow, he considered that the indication to leave the tubes was clear.

Dr. J. W. BALLANTYNE thought a small dermoid with twisted pedicle on the right side might be confused with salpingitis, and that accurate diagnosis was often impossible until the abdomen was opened.

Dr. HARG FERGUSON thought it was better to delay operation in acute salpingitis unless there was general peritonitis. He was not in favour of leaving a leaking tube, gonorrhoeal or otherwise. He had generally found that tubal conditions gave sufficient pelvic indications for a fairly accurate diagnosis.

Dr. WEBSTER told of a case of spinal curvature treated by gymnastic exercises on the trapeze. There was a complication of general and severe chronic bronchitis, and this entirely disappeared after two months' treatment.

Dr. J. D. COMRIE corroborated Dr. Fleming's results from his own experience. In one old lady of 75, with severe pleurisy and bronchitis and in a very grave condition, propping up in bed, encouragement of coughing, and the stopping of sedatives were followed by recovery.

ETIOLOGY OF RICKETS.

At a meeting of the Royal Medico-Chirurgical Society of Glasgow, held on February 3rd, Dr. HARRY S. HUTCHISON made a communication on "Rickets in India," and referred at length to his investigations in the town of Nasik, Bombay Presidency. Here there are two distinct classes of the population: Class 1, chiefly Brahmmins, well-to-do Hindus, and well-to-do Mohammedans; and Class 2, lower caste and poorer Hindus, poor Mohammedans, and social outcasts. The general conditions in both are the same, but they differ in that Class 1 maintains purdah, or the close seclusion of women and children during part of their lives. This class has a good and rich dietary, whereas Class 2 has no purdah and eats a poorer dietary. All children are breast-fed for at least a year; in Class 1 this is supplemented with cow's milk at the age of 7 or 8 months, and in Class 2 with rice, and seldom with milk. The mothers of Class 1 eat a dietary containing more vitamin A than those of Class 2, and therefore it would appear that the children in Class 1 get more vitamin A than those in Class 2. The incidence of rickets was found to be much more common in the Brahmmins and well-to-do Hindus in Class 1; less so, but still marked, among Mohammedans, partly in Class 1 and partly in Class 2; slight in other Hindus, all in Class 2. Of 1,073 children of purdah mothers there were 268 cases of early active or healed rickets (24.9 per cent.), and of 2,305 children of non-purdah mothers 113 cases (4.9 per cent.). Seventeen cases of late rickets were seen in air histories gone into. All occurred in females; 16 cases in Brahmmins, well-to-do Hindus, and Mohammedans; only one case was in a lower caste woman, although many more of these were seen. In practically all the cases milk and ghee were consumed daily, and frequently a cow was kept. The mean age of incidence was 15.6 years, the majority being between 12 and 13 years. Dr. Hutchison discussed his results with regard to the etiology of rickets, and concluded that in his cases the presence of quantities of vitamin A seemed to be unavailing in preventing the onset of rickets in the class referred to, whereas in the poorer classes, without such quantities, the plentiful supplies of fresh air and sunshine very largely prevented its incidence. Cases of active rickets treated by fresh air and sunshine improved rapidly.

Professor NOEL PATON made a communication on "Rickets, the part played by unhygienic social conditions in predisposing to the disease." Professor Paton said that two factors predisposed to the onset of rickets—unhygienic surroundings and defective feeding. Recently an attempt had been made to prove that it was caused by the absence of a hypothetical antirachitic factor, probably identical with the fat-soluble A substance. The author of this contention had now abandoned this view, and had reverted to the long-accepted theory that various errors of diet predisposed to rickets. The evidence of the influence of social condition had received scant attention from those who maintained the causal relation of the dietary factor to the disease. Rickets was common among the poorer classes of our northern towns, where they were housed in high tenements defective in light and ventilation. The condition of the house depended largely upon the health and habits of the mother, as did the extent to which the young children were taken out. A table was shown proving that, in Glasgow at least, the incidence of rickets was more directly associated with the condition of the home, with maternal care, and with overcrowding than it was with dietary. Between families with rickety children and those without the differences in the food were small. It had been argued that the absence of rickets among the people of Lewis, who lived largely in the so-called black houses, strongly supported the view that insanitary conditions of housing had nothing to do with a predisposition to the disease. An investigation of the housing, mode of life, and of the diet of eighteen typical families in the island had been made, and the results showed: (1) That the average air space and ventilation of the black houses was better than that of the rachitic families in Glasgow; (2) that the

children were taken out when quite young, and that after they could walk they were constantly out of doors. The development and nutrition of the children showed an average well above that of the rest of the British Isles. Teething was early, and generally the infants walked at an early age. Only one case of doubtful rickets among eighty-one children was observed. The diets were ample, and the chief articles of diet were fish, milk, oatmeal, and potatoes. The condition of these people, not only as regards diet, but also as regards housing and mode of life, was such as to increase their resistance to the onset of rickets. Professor Paton stated that his studies of rickets had led him to the conclusion that the unhygienic conditions of life and defective diet were more the causes of rickets than they were the causes of tuberculosis or of typhus. They merely predisposed to these diseases. Whether rickets would prove to be an infective process remained to be seen. Its association with slum life, its frequent incidence in several members of a family, and the record of an outbreak among foxhound puppies, checked in the case of some by removal to new kennels, suggested this possibility.

ALIMENTARY TOXAEMIA IN NERVOUS DISORDERS.

THE Hunterian Oration of the Hunterian Society was delivered on February 22nd by Dr. THEODORE THOMPSON, who took for his subject "Alimentary toxæmia in nervous disorders." The effects of alimentary disturbance, he said, operated on three levels of the nervous system—namely, peripherally, in the spinal cord, and in the brain. In connexion with the first of these he spoke at some length of alimentary influences in diphtheritic paralysis. He also said that peripheral manifestations of alimentary toxæmia might occur in the case of poisoning by food, and mentioned a case of which he had experience of a man who, as a result of eating sausages sent from Germany, had severe vomiting and alimentary derangement, which was followed by bilateral facial paralysis, with strabismus, and later on loss of knee-jerks and weakness of the limbs; the patient eventually recovered. The results of pure starvation experiments of recent years appeared to show that polyneuritis was not caused by a complete deprivation of food (and therefore, of course, of vitamins), but only by an unsuitable kind of food, such as polished rice in beri-beri, and it seemed to him very likely that the polyneuritis of beri-beri was analogous to that produced in diphtheria.

Turning to the group of spinal cord diseases characterized by more or less rapidly developing spasticity and ataxia of all four limbs Dr. Thompson said that these included the condition commonly known as subacute combined degeneration of the spinal cord, also the posterior lateral degeneration found in cases of pernicious anaemia, the spinal cord changes occurring in certain cases of grain poisoning, and, finally, pellagra. He proceeded to deal with each of these from the point of view of alimentary toxæmia, and pointed out that in pernicious anaemia the evidence of gastro-intestinal toxæmia was particularly marked. The tender spots about the mouth and tongue which occurred so constantly in the early stages of pernicious anaemia were frequently followed later on by persistent vomiting and sometimes by diarrhoea, and there was evidence to suggest an intestinal toxæmia as the cause of the disease.

With regard to alimentary toxæmia in brain diseases, the possibility that the alimentary tract was the site of infection for certain acute diseases of the brain had received striking confirmation by the examination of the sources of infection in cerebro-spinal fever. So important had the bacterial invasion of the nasopharynx become in the case of cerebro-spinal fever that the routine examination of the nose and throat should always be insisted on. Again, the connexion between rheumatism and chorea had now been definitely established. The view that rheumatism must be due to an invasion of the body by an intestinal streptococcus was gradually becoming widely held. It had been suggested also of late years that many of the degenerative diseases of the brain and spinal cord were the result of chronic intestinal infections. The possibility of a toxic effect in general nervous exhaustion had been much debated. The tendency to look to purely psychological factors had resulted in much unnecessary suffering for many patients. Pyorrhoea and chronic septic absorption from the roots of the teeth were responsible for many of the symptoms of mental and bodily exhaustion. Chronic septic

conditions of the tonsils should never be overlooked. In the treatment of nervous disorders from the point of view of alimentary hygiene particular attention should be paid to the mouth and associated cavities. The condition of the accessory nasal sinuses and of the tonsils should be explored. Over-consumption of meat and of sugar should be avoided; the taking of copious amounts of fluid was of assistance in alimentary toxæmias, and where the colon seemed to be the seat of the alimentary poisoning lavage of the large intestine was useful.

It is not customary to have discussion after an oration, but in expressing the thanks of the Society to the orator Dr. ANTHONY FEILING took occasion to agree with him in what he had said about beri-beri as being possibly not, after all, a vitamin-deficiency disease. Dr. Feiling had seen a localized epidemic of beri-beri among Chinese labourers in Mesopotamia. The epidemic was confined to men who lived in one out of several huts, and the diet of these men had been carefully devised to include as much vitamin-containing substance as possible, in addition to which they were accustomed to buy fresh food on their own account out of their considerable earnings, and yet the epidemic developed.

THE TREATMENT OF TUBERCULOUS GLANDS.

At the meeting of the Medical Society of London on February 27th, Mr. JAMES BERRY presiding, a discussion took place on the treatment of tuberculous glands.

Mr. G. GREY TURNER, in opening, said that on looking back upon the history of the treatment of tuberculous glands the most striking fact was the absence of any pathological basis for the various plans of treatment. There were two main routes by which tubercle might reach the glands in the neck: (1) infection from the nasopharynx; (2) infection through the mesenteric or mediastinal lymphatics. The evidence for the first of these routes was well known and incontrovertible. On the clinical side there was the association of enlarged glands beneath the upper third of the sterno-mastoid, commencing with a definite throat affection or associated with obvious pathological enlargement of the tonsils or with adenoids; and on the pathological side there was the frequent discovery of the tubercle bacillus both in the lymphoid tissues of the tonsil or adenoids and in the involved glands. He submitted that the infection of the glands usually occurred during the first two years of life, though it might not be until long years afterwards that the tuberculous infection of the glands became a prominent feature. In the second method of infection what happened was that the infection of the internal glands took place during childhood, presumably during the first two years of life, as the result of the ingestion of food—usually cow's milk—containing living bacilli. At any time subsequently, but usually during the critical period of adolescence, the tubercle declared its vitality, and the infection spread to the glands, it might be only in the neck, or in other situations. The glands which became enlarged in this way were usually in the lower part of the neck, and quite commonly in the posterior triangle. As direct evidence on the route of infection he mentioned that on several occasions, when dissecting the lower part of the posterior triangle, just beneath the clavicular head of the sterno-mastoid, he had removed one or more glands which contained black pigment characteristic of mediastinal infection.

After dealing with the infection of the axillary and groin glands and other and mixed foci of infection, the speaker referred to the principles which should govern the management of the different groups of cases. In the first group, with the infection from the nasopharynx, a local condition was being dealt with, and the surgeon had here a wonderful opportunity of dealing radically with the focus of infection and the commencing invasion of the lymphatic system. The ideal treatment was to remove the tonsils and adenoids, and at a subsequent sitting systematically and thoroughly to clear out the whole group of infected glands. But in the second group, where the infection had arisen from the mesentery or in the mediastinum, the problem was entirely different. Here they could neither deal radically with the focus nor with the greater part of the disease, but it must never be forgotten that such patients developed tuberculosis of the glands of the neck or elsewhere because their resistance to tuberculous invasion was so far lowered that the bacilli had got the upper hand. The proper treatment was then to raise the resistance of the individual as far as possible; in this group therefore surgical intervention was not the

primary requirement, but it might none the less be an adjunct.

The speaker went on to deal with the clinical features of these different groups, and gave some illustrative cases also touched on operative technique. No operation surgery were more important than those on tuberculous glands. The incision must be so planned as to leave the possible scar, but at the same time must be adequate enough to enable the dissection to be carried out without hampered for want of room. Whenever possible the incision should be made in the normal creases, or at least in the same direction. Extensions of any incision should either be made up into the hair line, where they were usually behind the sterno-mastoid. When excision was contemplated the surgeon should remove all the lymphatic glands infected otherwise from the area which was attacked. This extirpation must be thorough and complete, but it was not wise to attempt to remove all the lymphatic glands in the anterior triangle of the neck, for instance, from an incision which was only planned to expose the upper part. In other words the surgeon should stick to some one area, and should clear out very thoroughly. He dealt at length and precisely the operation for the removal of the tonsillar group of glands which he described as the ideal operation, because this was the situation in which it was usually possible to remove the focus of infection with the whole of the consequences of infection.

Mr. Turner, who confined his remarks to surgical methods, finally gave the results of an investigation into the history of 143 cases operated on for tuberculosis of the glands. The inquiry was made from five to eighteen years after operation, and replies were received regarding 83 of the others being untraced. These 83 were classified as follows:

Perfectly well	54
Good health, but small glands near operated area	15
Alive, but with other groups of glands involved	4
Alive, but with other tuberculous manifestations	2
Died of tuberculous disease	6
Died from other causes	2

Of these cases, 63 belonged to the nasopharyngeal group and 20 to the mesenteric; 60 in the first group and 9 in the second were perfectly well or greatly improved. Very few scars were obtained in 50 of the nasopharyngeal group of cases and 5 of the mesenteric group.

Sir LENTHALL CHEATLE was not prepared on the spur of the moment to accept Mr. Turner's statement—that when tuberculous glands appeared at the base of the neck they were possible "outriders" of mediastinal or mesenteric tuberculous infection. It seemed to him quite possible that in the cases Mr. Turner had brought before them he was really dealing with nasopharyngeal infection, not only in the neck, but even in the mediastinum and in the intestinal tract. He agreed that tonsils and adenoids were a frequent source of infection; of the reasons for the rarity with which operations on tuberculous glands of the neck now took place was the free removal of tonsils and adenoids in children in childhood. It was possible, however, for the tubercle bacillus to get into the glands of the neck without infecting the tonsil, and also to have tuberculosis of the glands of the neck after the tonsils had quite recovered from the infection. It was not, therefore, a very important piece of evidence whether or not the tonsils were tuberculous; although, of course, a positive finding here was very significant. He indicated his methods of treatment of the different stages of tuberculous glands. In the stage in which the tubercle bacilli had caused ulceration outside the lymphatic glands his custom was to open the abscess, squeeze out much of the tuberculous and caseous material as he could through a small incision, and then wait a fortnight or a month before excising the gland.

Mr. W. H. CLAYTON-GREENE, speaking as a general surgeon, remarked on the rarity of infected glands in the neck compared with the numbers of cases he saw twenty years ago. In those days they accounted for an average of one every ten cases in his wards; to-day it might be putting it too high to say that he had one case in three months. The reason for this comparative rarity was the attention which was now paid to local irritative lesions in the tonsils, and adenoids. It had been assumed that the diagnosis of tuberculous glands was easy, but to him it was extremely difficult. Many cases were treated as tuberculous glands which were not so at all, and except for the process of time he did not know any means of accurate

diagnosis. Three more or less distinct types of the disease might be recognized: (1) the single gland; (2) scattered glands all about the neck; (3) the matted type, where the glands were adherent to all the surrounding structures. In the first type, especially in the case of young girls, if he saw the case at a stage when the gland was softening and breaking down, he found it best not to excise the whole gland, but to puncture and scrape. In the third group he had found x rays of distinct value; they were useful also where sinuses persisted after an imperfect removal of the gland. He had had no success personally with tuberculin, though he was aware of striking success by others. On the other hand, he had had very good results from sending patients for open-air treatment. As for mesenteric tuberculous glands, here again he found considerable difficulty in arriving at a diagnosis. He had, however, come across a number of cases in which colic had occurred in association with such a condition, and a preliminary diagnosis of tuberculous glands had been suggested by the multiplicity of attacks of colic, often reaching back to childhood. These mesenteric glands were a very serious source of danger, because, both in the caseous and the calcifying state, so frequently the cause of obstruction. His method of treatment was to remove them, unless in doing so he was likely to interfere with the vascularity of the bowel, but the removal was done rather in the hope of getting rid of a source of obstruction than of extirpating completely a tuberculous focus. He believed in the great recuperative powers of the body against tuberculous infection. Perhaps it was a traitorous act on the part of a surgeon to confess that nature might sometimes be more potent than the knife; nevertheless, that was his belief, and the more he came into contact with surgical tuberculosis the less readily did he adopt active surgical measures.

Mr. WARWICK JAMES said that as a prophylactic measure the treatment of the teeth was of the utmost importance. Tubercle bacilli had been found in the debris around the teeth, but whether in individuals who did not have a tuberculous infection elsewhere was not clear. The histological demonstration of tuberculous lesions in the mouth had only been made in very rare instances. He did not think that the clinical evidence favoured the view that the mouth might be the portal through which the organism reached the glands. Many of the patients whose portraits Mr. Turner had shown them that evening were mouth-breathers; unless mouth-breathing was corrected, a source of irritation to the glands was likely to continue. He believed that the diminution in the number of operations now found necessary upon tuberculous glands was due to the care exercised by the laryngologist and dental surgeon in removing sources of irritation.

Sir HENRY GAUVAIN said that he rarely found cases in which large tuberculous glands were the only tuberculous lesions, but he was greatly struck by the number of cases which came to the Children's Hospital at Alton with sinuses and very frequently scrofuloderma following operation. He believed in conservative methods of treatment. He rarely used the knife, and did not see any great reason why he should. It was not simply a question of fresh air and sunlight, but of the employment of these agencies in carefully thought out ways. It did not always follow that the seaside was the proper place for these children; the younger children, up to the age of 5, did better in the country. Much might be done by sun treatment, but one should not start with the sunning of the glands themselves; the treatment should be commenced at the feet and gradually extended over the body. Sea-bathing was of immense value in many cases among older children and adults. As for minor measures, in cases where there was one large gland containing pus, he had often been able by a simple aspiration to empty it; if aspirations were required frequently he had a leaning towards a method of treatment which might not be good surgery, but was extremely effective—the putting of a seton through the gland and leaving it in place for a fortnight or three weeks. This induced a leucocytosis in the gland, without sepsis, and cleaved up the caseous material, and when the seton was removed there were but two small punctures left, an even smaller scar than in Mr. Turner's cases. Masses of tuberculous glands with much pre-adentitis did best by x rays, which were also useful with sinuses, though not infrequently there was at the bottom of the sinus a little piece of caseous material which acted as a sequestrum and had to be removed before the sinus would heal. He mentioned in passing a case of two young Siamese students recently under his care—their race was to be noted, because he believed the Siamese less resistant than English people—with mesenteric glandular

affection, one of the cases being followed by spinal caries and the other by sterno-clavicular tuberculous.

Mr. W. G. HOWARTH believed that in a number of cases the portal of infection was the tonsil, and the proper line of treatment in all well-marked cervical adenitis was to remove this source of infection, when, in a large number of cases, the adenitis would disappear. With regard to the infection of the tonsil itself with tubercle bacilli, his own investigations over a series of several hundreds of cases revealed only 5 per cent. of cases of enlarged unhealthy tonsils associated with cervical adenitis in which there were tubercle bacilli in the tonsils. He wondered why surgeons were so chary about doing aspiration. When a gland was softened it was quite a good and legitimate surgical procedure to put in a sterile needle and withdraw the fluid; the natural resistance of the body was then often sufficient to overcome the infection. When sinuses existed he had had good results with x rays.

Mr. DUNCAN FIRZWILLIAMS protested that if it was desired to get rid of the condition quickly, aspiration would not prove successful four times out of five. A deep-seated focus of infection could not be removed by mere aspiration. It was much better to make an incision and clear the whole focus out. With regard to scars, it was possible to excise them very easily and prevent the unsightly conditions sometimes witnessed, due to lack of platysma. One simply put in the tenotome, freed the scar, so that it came clean up from the underlying tissue, and then removed a flat piece of fat from the back, which could be easily slipped in to supply a false platysma.

Dr. LAPHORNS SMITH said that in his experience among tuberculous children, sunlight in the country was better as a rule than sunlight at the seaside.

Mr. GREY TURNER, in replying, said that he was quite sure the tuberculous organism could get into the body through the tonsil or through practically any mucous membrane without leaving any trace behind. If they looked for tubercle in the tonsil at the stage of the acute infection—not when the condition had been present for a long time—they would find it much more frequently. Some speakers had suggested that there was a stage in tuberculous gland lesions when only a single gland was affected. This might be the clinical picture, but on pathological examination groups of infected glands would invariably be found. He was perfectly certain that one never got only a single gland infected. He admitted that amelioration and perhaps cure were possible among many lines of treatment, but he doubted the permanency of many of the results. Certainly more evidence was needed, and the cases should be traced over a longer period of time before a cure could be definitely claimed. Practically all forms of surgical tuberculosis, if only enough time could be spent upon them, could be overcome by natural means. That was why Sir Henry Gauvain could speak so optimistically; he was working at Alton under most fortunate conditions. It was said that the number of cases of tuberculous glands had greatly diminished. Nevertheless, the speaker saw many cases still, although tonsillectomy was actively pursued in his district. The reason why these cases did not come into wards was the pressure on accommodation. Finally he protested against operation in these cases being treated as minor surgery. These cases should not be crowded in at the end of the surgeon's long and tiring list. He recalled that when C. B. Lockwood went to lecture at Newcastle on amputations he advised a surgeon who was undertaking his first operation that the most important thing was that he should have a good meal beforehand. The same advice might be given to those about to operate on tuberculous glands. The task should be approached with a feeling of contentment and well-being, combined with a wholehearted belief in the measures adopted.

THE sixth annual meeting of the Japanese Medical Association was held at Tokyo on November 25th and 26th, 1921, under the presidency of Dr. Kitasato. Among the resolutions adopted was one for the establishment of a board for the prevention of the sale of patent medicines, and another demanding a Government inquiry into the best measures to be adopted for the prevention of venereal diseases.

A BILL has been introduced into the New York Legislature forbidding a male doctor to treat a female except in the presence of another female. The bill was introduced by Mr. Male. The *New York Medical Record* describes it as one of the comic reliefs of the popular legislative meddling in medical matters; and the New York Medical Association has passed a resolution disapproving of the bill "unless it could be amended so as to work also the other way round."

Rebicus.

EXPOSURE OF DEEP-SEATED VESSELS.

RELATIVELY few surgeons are acquainted with the admirable work of FIOLE and DELMAS on the rational exposure of the deep-seated blood vessels, but the English translation of their book, which has recently appeared, should ensure a wider familiarity.¹ It is a fact that certain of the classical incisions and methods of approach are totally inadequate, especially in the wounds of war. Free exposure and an unhampered operation field are essentials in these cases, whether suture of the vessel or simple ligation is the object. And since these desiderata are equally to be sought in times of peace, much that is written in this book may advantageously be transferred to civilian practice. Not only are several of the common routes for exposure revised, but some ingenious operations have been thought out for the exposure of parts of vessels usually left untouched.

The ligation of the blood vessels of the posterior aspect of the leg is first described, and, indeed, most of the real innovations in technique are for vessels of the lower extremity. The classic procedure for exposure of the posterior tibial vessels is difficult indeed, as many unfortunate candidates for the higher diplomas in surgery have reason to know. Fiole and Delmas replace the usual operation by an incision through the middle of the calf, dividing gastrocnemius and soleus; this gives a good view of the vessels of the calf and posterior tibial nerve. Two new operations have been invented to give access to the upper part of the anterior tibial artery in the interosseous space, and the origins of this and the posterior tibial from the popliteal. A noteworthy feature is the attention paid to anatomical reconstruction, both in the discussion of the proposed route and in the paragraph which closes each chapter. Probably the best of the new operations, in addition to those already mentioned, are those for exposure of the junction of the femoral and popliteal arteries and that for the display of the sacro-sciatic notch and gluteal vessels, not to mention the great sciatic nerve. The views expressed with regard to the remaining vessels discussed—those in the upper third of the forearm, in the axilla, in the root of the neck, and the carotids—are not so unusual as those in the lower limb.

The book has been translated and edited by Dr. C. G. CUMSTON of Geneva, and the fastidious will find a few faults with the translation. For instance, "detachable space" for "l'espace décollable" is bad, and "presolar" for "présolaire" is not very happy. Compare also the following: "Now, if he be lacking in coolness, he will apply haemostatic instruments haphazard on muscle, nerves, etc., or, what is more likely, on nothing at all, so that the patient becomes exposed to terrible risks," with the original, "S'il manque de sang-froid, il pince au hasard muscles, nerfs, ou rien du tout, et le blessé court les plus terribles risques." It will be noted that the authors did not say that the operator is more likely to pick up in his forceps "nothing at all." This is apparently an addition of the translator's own, and the addition does not state a fact in accordance with probability. Whether a translator, even though he be editor too, is wise in making small alterations and additions to the text is a question for individual judgement. But the original text of MM. Fiole and Delmas is so clear, so well planned, so excellently expressed, that those who know it well may be excused a little impatience at unnecessary alteration.

The translation is well printed, and the very clear and helpful illustrations of the original French edition have been skillfully reproduced. Altogether this book is a notable achievement.

TREATMENT OF DIABETES.

PROFESSOR CARL VON NOORDEN has written a pamphlet on the present position of diabetic therapeutics,² giving a summary of the treatment of diabetes as practised in Germany to-day. In the years before the war von Noorden was a leading authority on the subject, and his work had a great influence on the development of the modern treatment of diabetes. Then came the war; Germany was cut off from other nations,

and by herself made no further progress. The rest of the world went on. When peace came Germany had been left behind. The German books on diabetes published after the war are old-fashioned to English ideas. Von Noorden makes a gallant attempt to assimilate the old German alternations of oat and other carbohydrate "cures," vegetable days, full diet and hunger days, with the modern far more precise and practical Allen scheme of treatment. He admits its excellence, but is of opinion that the course is unnecessarily severe in the majority of cases. Professor von Noorden does not accept the view that tolerance is raised by a period of under-nutrition, and consequently disapproves of the long continuance of diets in which the patient does not receive the number of calories theoretically necessary. Apparently he does not accept the conclusion to be drawn from the experiments of physiologists that in under-nutrition the body when at rest uses fewer calories than in the normal condition; at the same time he shows that he is fully aware of the dangers of overfeeding, and utters several warnings on this head. He seems not to have read Allen's latest publications, for some of his criticisms are directed against points already modified. The recent work on the relation of body weight to tolerance and on the effects of exercise is not alluded to. Professor von Noorden advocates Allen's treatment in all cases where the control of hyperglycaemia, glycosuria, and ketonuria is urgent; but he evades what seems to us the main point—namely, that Allen's diet affords a far better means than any other for testing the patient's tolerance and keeping a watch on his progress.

In laying down rules for the definitive diet von Noorden's plan is to alternate carbohydrate days, vegetable days, and days with full protein diet, the quantities given being of course adjusted to the individual patient's requirements. The plan would appear to be effective in the majority of cases, though it seems to us a rather complicated one. It is difficult for a patient to lead a normal life on this diet. In this respect the method of testing the patient's tolerance, and then giving him a list of foods (with their protein, carbohydrate and fat equivalents) from which he may choose, has the advantage. The pamphlet ends with a timely reminder that no one method is suitable for all cases and that the individual diabetic must be studied—not merely his disorder. When men cling to a stereotyped rule in the treatment of disease the end is sterility and failure. Von Noorden acknowledges no rules, but he never loses sight of fundamental principles. If he has succeeded in impressing his ideals on the rising generation his work will not have been in vain.

THE BACTERIOPHAGE.

DR. F. D'HERELLE believes that he has discovered an ultramicroscopic organism which is a parasite of bacteria, and he gives a full exposition of his views in a monograph of the Pasteur Institute entitled, *Le Bactériophage, son Rôle dans l'Immunité*.³ It is based on researches carried out since 1917; many of the records have been published separately, but the book contains a fuller statement of the author's views. The book begins with a statement of the fundamental experiment on which the theory of the bacteriophage is based—namely, that a filtrate from the stools of a patient with bacillary dysentery (Shiga) when added to a fresh broth culture of Shiga's bacillus causes lysis of the bacteria, and that a drop of fluid from the culture so treated can produce the same change in a fresh suspension of dysentery bacilli. D'Herelle believes that he is dealing with an ultramicroscopic parasite of bacteria, so small that it will pass through the finest filter. This "bacteriophage," as he calls it, can only thrive on living bacteria, in the substance of which it grows and multiplies, becoming more and more virulent.

The first half of his book purports to describe the manner of life of this ultramicroscopic parasite, and relates the method adopted for estimating its activity, the distinguishing features of its cultures, and the influence of the reaction of the medium on its growth. An account is given of the effect of antiseptics on the life of the parasite and the manner in which it behaves in suspensions rich and poor in bacteria. The bacteriophage, we are told, exerts its lytic action through the agency of a powerful ferment which it secretes. The author has watched infected bacteria under the microscope, and describes how they assume a spherical form and finally

² *Über den jetzigen Stand der Diabetes-therapie*. Von Professor Carl von Noorden. In Frankfurt (Main). Munich and Wiesbaden: J. F. 1921. (Med. 8vo, pp. 42. M. 6.)

³ *Le Bactériophage, son Rôle dans l'Immunité*. Par F. d'Herelle. Monographs de l'Institut Pasteur. Paris: Masson et Cie. 1921. (Roy. 8vo, pp. 227; 12 figures. Fr. 12 net.)

rupture, liberating the enclosed bacteriophages. Bacteria develop protective processes against these intruders in the same way that human beings develop antibodies against bacteria. Resistant bacterial races are described, then acquired resistance being associated with altered morphology and culture characteristics. To make the analogy complete, there are even bacterial carriers of the bacteriophage!

The second half of the book deals with the part the bacteriophage is believed to play in immunity. Here we are presented with even more revolutionary ideas. In the early stages of an infection, d'Herelle assures us, our chances of recovery depend on the presence of this enemy of bacteria. If the bacteriophage is present the bacteria are attacked and destroyed; if absent, the bacteria multiply and cause disease. The human body is no more than the battlefield where the struggle rages between bacterium and bacteriophage. It is only in the later stages of disease that the antibodies developed by the human subject play any part, for they take many weeks to appear. The ups and downs of an illness are an indication of the fortunes of the rival forces. In an epidemic, also, the disease dies down and disappears because of the triumph of the attendant bacteriophage. Unfortunately, we are not able to fortify ourselves by keeping a stock of well-disposed bacteriophages ready at hand in case of an illness. Injected into the body they are eliminated at once, for they are only able to live on living bacteria. Still, it is comforting to reflect that the bacteriophage is very abundant throughout the natural world, and is as likely to gain an entrance as is a pathogenic bacillus.

Conceptions so far removed from current ideas sound fantastic. But the fundamental facts of the lysis of bacteria by filtrates from organic matter have been verified by many observers. We are in the presence of most important phenomena hitherto unexplained. Whether we accept d'Herelle's theory or not, it is obvious that the power of producing lysis of bacteria is a property which deserves very great attention. Further research will show whether this property is dependent on an ultramicroscopic parasite or due to a ferment secreted by cells. In the meantime this exposition of d'Herelle's views will be welcomed by all who study bacterial life, to whom we commend it.

SURGERY IN SOUTH AMERICA.

DR. FRANKLIN H. MARTIN, Director-General of the American College of Surgeons, paid two visits to South America, the first in the winter of 1920, when he was accompanied by Dr. William J. Mayo of Rochester, then President of the College, and the second in 1921, when his fellow-traveller was Dr. Thomas J. Watkins of Chicago, a Governor of the College. On this trip Dr. Martin and Dr. Watkins were eventually joined by Dr. F. P. Corrigan, a Fellow of the College, who had started rather earlier and paid visits to Ecuador and Bolivia.

The primary object of the trips was to confer with the surgeons of the several South American states with a view to their submitting names for election as Fellows of the American College of Surgeons. The missions in this respect appear to have been highly successful. The secondary object, more or less personal to Dr. Martin, was to induce the authorities of the various states to take an interest in the establishment of an Institute of Tropical and Preventive Medicine in Panama as a memorial to the late Surgeon-General Gorgas, whose organization of the system for preventing malaria and other tropical diseases in the canal zone made the completion of that great enterprise possible, and marks an epoch in the history of tropical medicine. To Dr. Martin's success in interesting the Presidents of the several republics in this project we owe the introduction of their portraits into the volume he has compiled with the title, *South America from a Surgeon's Point of View*; it is in other respects copiously illustrated with portraits of eminent surgeons and photographs of interesting buildings and scenery. In a chapter describing the journey across the Andes—in the composition of which Mrs. Martin had a large share—interesting accounts are given of the mountains and of the feats of the engineers in taking the railroad through them. The travellers started from the Chilean side, and the first part of the journey

was therefore a very stiff climb through rocky valleys and by foaming torrents. The descent on the Argentine side is more gradual and less striking. On arrival at Buenos Aires the travellers were met by a deputation of surgeons, who helped them to spend the next few days, partly in doing their particular business, but chiefly in sight-seeing; this is what happened to the party in all the cities they visited.

The reports on the state of surgery in South America are to the effect that it has attained a very high standard. In fact, Dr. Mayo seems to have been twitted with having found all swans and no geese. His reply is that life is too short to spend any of it in witnessing bad surgery; he is interested only in good, and looking for it in the chief cities of South America he found it. He says—and his colleagues agree with him—that the technique is modelled on the French, which means that a great deal of what is done for the surgeon in North America and Great Britain by nurses has to be done in South America by his surgical assistants owing to lack of trained nurses. The two chief criticisms to which expression is given are indeed that the nursing in the hospitals is not good, and that not sufficient care is taken to screen the wards against flies. The actual buildings are in many instances large and well designed, and so are those provided for the medical schools. The teaching is thorough, and the curriculum extends to seven years. Very few foreigners obtain the right to practise, owing, as we gather, to the strictness of the regulations and the severity of the examinations.

Dr. Martin takes a sanguine view of the future of tropical South America. The grounds on which he builds his hopes seem to be mainly two. First, he believes that the modern methods of prevention which have already yielded good results in coast areas can be applied generally in the interior. Secondly, if we have correctly understood a passage on page 130, he is of opinion that a race is being evolved in which the energy and enterprise of European stocks will be combined with the inbred powers of resistance to disease possessed by the aboriginal inhabitants.

The medical pilgrim in South America or the stay-at-home who wants to get an idea of the general features of that great continent and of the character of its peoples will not easily find better guidance than is provided in this volume.

COMMON FEMALE AILMENTS.

DR. F. J. MCCANN has published a little book entitled *The Treatment of Common Female Ailments*,² in which he offers to the general practitioner guidance in the treatment of gynaecological complaints, mostly those of a minor variety. All the common conditions are dealt with, and the essentials of diagnosis mentioned; the treatment is described in a most practical, and, where necessary, detailed fashion, which will make the book of value to practitioners who are not familiar with the methods of treatment. Numerous prescriptions are introduced, and these will be a boon to the practitioner who, from lack either of time or of intellectual energy, likes to have his therapeutic instruction provided in this ready-made fashion. Many of these prescriptions and some of the lines of treatment suggested are obviously suited only to patients of means. To this, of course, there is no objection; but surely even the leisured lady of means might be spared "at least ten days in bed" after a simple dilatation of the cervix. One of the best chapters in this little book is on "How to diagnose cancer in the womb," and its perusal should put the reader on the alert to recognize this condition while it is still in its early, and probably operable, stage. The subjects of abortion and puerperal infection have been included in the author's purview because of their preponderating influence in the causation of the more common female ailments.

Dr. McCann uses the appalling word "sacrache" for pain over the sacrum. If he objects to the word *sacralgia* as a hybrid, that is no justification for perpetrating another hybrid which has the additional objection of a hideous cacophony.

Moderately priced and well printed, this small book cannot be read without profit, and we are quite sure that it will make a strong appeal to many of the practitioners to whom it is addressed.

¹ *South America from a Surgeon's Point of View*. By Franklin H. Martin, C.M.G., M.D., F.A.C.S. With an Introduction by William J. Mayo, M.D., F.A.C.S. New York, Chicago, London, and Edinburgh: Fleming H. Revell Company. (Cr. 8vo, pp. 325; illustrated. Price not stated.)

² *Treatment of Common Female Ailments*, by Frederick John McCann, M.D. (Edin.), M.R.C.P. (Lond.), F.R.C.S. (Eng.). London: Edward Arnold and Co. 1922. (Demy 8vo, pp. 152. 8s. 6d. net.)

NOTES ON BOOKS.

Dr. W. E. FOTHERGILL'S *Handbook for Midwives and Maternity Nurses*⁶ has reached its fourth edition, a proof of well-deserved popularity. The book is written throughout with the lucidity which is characteristic of Dr. Fothergill's style, and forms a useful textbook for nurses studying for the examinations of the Central Midwives Boards. The illustrations are good, and we are particularly glad to see the space which is devoted to the anatomy of labour—the numerous frozen sections which are illustrated being calculated, with the assistance of the text, to give the reader a clear idea of what actually occurs during labour. There are various appendices dealing with the regulations of the Central Midwives Boards and a number of test questions which have appeared in the examinations of the Boards. The book can be cordially recommended.

Dr. RAMSEY'S *Care and Feeding of Infants and Children*, now in its second edition, is a textbook for nurses. The first half of the book contains an adequate account of the anatomy and physiology of the child, and gives full details of the way in which the normal child should be fed and brought up. In the second half the chief disorders and diseases to which infants and children are liable are discussed briefly. The book is well illustrated, and the author writes with clearness and decision. The volume may be warmly recommended to intelligent mothers and nurses who wish for a sensible guide to the upbringing of infants and young children.

From Dr. K. UTHOFF'S small book on the fate and care of the blinded soldier⁸ it appears that there are in Germany about 4,000 soldiers blinded in the war. He gives an account of what is being done for them; some 2,000 fully trained leading dogs have been found, and a demand for 1,000 dogs a year is contemplated. Special chapters are given to the trades and occupations deemed suitable for the blind. The book is well written and should be in the hands of all who have the blind soldier's interest at heart.

MEDICAL AND SURGICAL APPLIANCES.

A Urethroscope Tube for the Posterior Urethra.

CAPTAIN F. CARMINOW DOBLE, R.A.M.C., writes: The difficulty in obtaining a simple urethroscope, by means of which one can examine the posterior urethra, has no doubt been experienced by many surgeons. I have recently had a special tube fitted to my "Holborn" urethroscope, by means of which one can get a very clear view of the floor of the posterior urethra. The urethral tube, as illustrated, is rather more than $\frac{7}{8}$ inches long and of 25 French catheter gauge. It is curved at the end, and has an opening $\frac{1}{2}$ inches long in the convex surface of the bend. This opening is completely filled by the pilot when introducing the tube, and I find it causes very little bleeding and discomfort to the patient. The tube is made to fit the body of the "Holborn" urethroscope, and lengthening pieces are supplied for the lamp holder and instruments to make up for the extra length of the posterior tube. The lens used is a large single one $\frac{7}{8}$ inch in diameter, and does not require any adjusting or focussing, which

is necessary with the more complicated and expensive instruments, and one can get a very much better view. The tube can also be used with the operating body, thus enabling one to carry out in the posterior urethra any necessary treatment as easily and with just as good an illumination as in the anterior urethra. It is advisable to give the patient a $\frac{1}{4}$ grain belladonna suppository the night before and another an hour before the examination and to wash out the bladder with mercury oxycyanide afterwards; a local anesthetic is rarely necessary. After the patient has passed water the tube is introduced as if it were a sound and the pilot removed. The mucous membrane is then dried with mounted swabs and the body of the instruments attached. The illumination is very brilliant. A little care and practice is necessary to prevent the window being pressed on to the mucous membrane. By gently withdrawing the tube and rocking from side to side, the walls and floor of the posterior urethra can be examined.

RADIUM THERAPY.

ANNUAL REPORT OF THE LONDON RADIUM INSTITUTE.

The annual report of the London Radium Institute for 1921 differs somewhat in plan from the reports issued in previous years. Mr. A. E. Hayward Pinch, F.R.C.S., the medical superintendent, devotes the first part to a brief summary of the results obtained in the period of ten years that the Institute has been in existence. The second part of the report practically takes the form of a short monograph on radium therapy in gynaecology. Mr. Hayward Pinch has been responsible for practically the whole of the gynaecological treatment since the Instituto was opened, and his personal experience in that subject is most interesting, and forms a contribution to medical literature of high value. The last part of the report consists of a summary of the work of the research department, by Dr. J. C. Mottram, and a short report on the work of the chemico-physical laboratory, by Mr. W. L. S. Alton.

THERAPEUTIC VALUE OF RADIUM.

The London Radium Institute was opened in August, 1911, and since that time some 7,750 patients have been dealt with, and nearly 100,000 treatments administered. The cases treated fall into four chief categories:

(a) Those in which cure, either complete in the case of non-malignant, or apparent in the case of malignant, disease, may be confidently anticipated: Chronic eczema, seborrhoeic eczema, lichenification, cavernous naevi, keloids, papillomata, keratomata, corns, rodent ulcer, lympho-sarcoma, sarcoma of the nasopharynx.

(b) Those in which great benefit, both local and symptomatic, may be expected to ensue: Psoriasis, xanthelasma, xeroderma pigmentosum, Fordyce's disease, leucoplakia, capillary naevi, "port-wine" marks, spring catarrh, lupus erythematosus, lupus vulgaris, tuberculous adenitis, vicious cicatrices, Dupuytren's contraction (early stages), exophthalmic goitre, parenchymatous goitre, splenic leucocythaemia, lymphatic leucocythaemia, lymphadenoma, mediastinal tumours, epithelioma of skin, epithelioma of cornea, epithelioma of vagina, epithelioma of urethra (female), carcinoma of breast, carcinoma of uterus, carcinoma of bladder, carcinoma of prostate, carcinoma of thyroid, sarcoma (excluding endosteal), endotheliomata, angio-neurotic oedema, arthritis deformans (early infective cases).

(c) Those in which the result is doubtful, some cases responding very well, others of like character failing to show any improvement whatsoever: Pruritus, neuralgia, neuritis, epithelioma of tongue, epithelioma of mouth, epithelioma of fauces, epithelioma of larynx, epithelioma of oesophagus, carcinoma of stomach, carcinoma of intestine, carcinoma of rectum, myelomata, melanomata, glycosuria.

(d) Those in which radium treatment is practically useless: Dupuytren's contraction (late stages), kraurosis vulvae, adenomatous goitre, osteitis deformans, acromegaly, cysts, lipomata, enchondromata, osteomata, endosteal sarcomata, syphilis, locomotor ataxia, disseminated sclerosis, poliomyelitis, paralysis agitans.

While it would be perhaps unwarrantable to use the term "cure" when speaking of radium treatment in conditions such as the foregoing, yet Mr. Hayward Pinch believes that it can with reason be claimed that results have been obtained in the arrest of the progress of the disease and in the improvement of the patient's general health and comfort to a degree which cannot be excelled, and is rarely equalled by any other known medical or surgical measure.

"It is to be regretted," he says, "that within the past twelve months statements have been published in the lay press to the effect that radium was 'a failure,' and these appear to have originated in the pronouncements of some well-meaning but ill-informed practitioners concerning a subject of which they possessed but very little personal experience. As these statements are not infrequently alluded to by patients and their friends, it is obvious that considerable harm has been done by their dissemination, and it therefore appears desirable strongly to controvert the assertion. Radium is not a failure when used intelligently and scientifically, and applied to the treatment of those conditions which experience has shown are amenable to its action. No honest worker claims, or has ever attempted to claim, that radium is to be regarded as a panacea, or as a cure for malignant disease, and many years must elapse, and much more research and clinical work be done, before it will be justifiable to use the word 'cure' even in selected cases of malignant trouble. It is best, therefore, to speak only of 'arrest of the disease,' and this can truthfully be affirmed in very many instances."

RADIUM AND X RAYS.

In regard to the question of the relative advantages of radium and x rays in the treatment of disease, Mr. Hayward Pinch considers that each case must be separately and carefully considered before a decision is given. X rays, however, are generally to be preferred to radium when the condition is very widespread and large areas of the body are affected—for example, generalized psoriasis and the early stages of cancer "en cuirasse," generalized infection of the peritoneum, as met with in cases of cystic disease of the ovaries, etc. In all these conditions an enormous quantity of radium, mounted on numerous applicators, would be necessary adequately to radiate the whole affected regions at one sitting, but this can, however, be readily accomplished by means of an x-ray tube. On the other hand, when it is desired to give an intense dose over a small area—for example, rodent ulcer, small superficial epitheliomata, recurrent nodules after excision of the breast for carcinoma, endobeliomata of the prostate, and sarcomata in the early stages, etc.—radium should be advised, as by means of emanation applicators an extremely powerful dose can be administered to a very small area. Then, too, there are certain situations, such as the cavity of the uterus, bladder, larynx, oesophagus, stomach, and rectum, where it is almost impossible to give an adequate dose of x rays, but where by means of a suitable form of apparatus radium can be quickly, safely, and effectively employed. In young children and nervous patients the procedure associated with x-ray treatment often proves terrifying. With radium this difficulty does not occur; no pain, discomfort, or annoyance is occasioned by the application, and it is a common sight to see quite young children who are being treated for naevi or tuberculous glands, etc., playing with toys, the applicators being safely strapped in position.

Radium treatment, it is noted, is useless in all cases of disease affecting actual bone substance, whether malignant or non-malignant, and it is now the custom at the Radium Institute, when a patient suffering from rodent ulcer which has actually invaded the bony tissue applies for treatment, to recommend excision of the affected portions of the bone before any exposures are undertaken. With regard also to cystic conditions generally, it is stated that radium treatment is of little value, more especially if the cysts be large and tense. When favourably situated, however, the removal of the contents of the cyst by excision or aspiration, followed by the introduction of radium into the cyst cavity, may be utilized to induce inflammatory adhesions of the cyst walls, and so prevent its reappearance. Radium has no effect on fatty tumours, and surgical interference alone is to be recommended.

RADIUM EMANATION.

According to the report, the employment of radium emanation as a therapeutic agent is steadily increasing, and its field of usefulness broadens from day to day as its merits and advantages become more widely recognized. The manipulation of the emanation is a highly technical process, and necessitates the attention and services of a staff of specially trained physicists, whose measurements of its initial radio-activity and its subsequent variations can be relied upon absolutely. There is further the fact that the emanation can only be obtained from solutions of radium salts; the quantity is limited, and bears a strict relation to the amount of the parent salt.

Radium emanation may be employed for therapeutic purposes in three ways:

1. *By Inhalation.*—This method obtained a great vogue on the Continent in the years immediately preceding the war. Most of the spas and bathing establishments were provided with radium emanatoria—luxuriously equipped buildings containing rooms the air of which was freshened from time to time with small quantities of radium emanation and oxygen, or radium emanation only. Extravagant claims were made as to its therapeutic value in the treatment of widely differing forms of disease, but these have been only poorly substantiated by subsequent clinical observation, and it is an open question whether the greater proportion of the cures announced were due as much to the power of suggestion as to the physical effects of the radium emanation.

2. *By Injection.*—Radium emanation is dissolved in water and administered to patients daily for periods of six, nine, or twelve weeks or longer. The strength of the solution furnished by the Radium Institute is 2 millieuries per litre, and of this patients take 250 c.c.m. during each twenty-four hours. The principal conditions benefited by this form of treatment are arthritis deformans, glycosuria, arterio-sclerosis, and the extremely rare malady angio-neurotic oedema.

3. *By Inclusion in glass or metal tubes and containers,* used for the radiation of diseased tissues in precisely the same fashion as radium salt apparatus.

The idea is prevalent in some quarters that radium emanation apparatus is less effective than radium salt apparatus, but the report strongly emphasizes the fact that their therapeutical properties are identical. In addition radium emanation possesses certain special advantages. Being a gas it is both compressible and expansile, and these qualities are peculiarly valuable in the making of applicators, as it is possible to concentrate the radio-activity very greatly and to prepare a tube of equal activity to any given radium salt tube, but only one-twentieth of its size. This is of great value in the treatment of small malignant growths or tumours of recurrence, enabling an intensely powerful radiation to be given in a very small area. Further, the emanation possesses no intrinsic value, and should an emanation applicator be mislaid or destroyed, the only pecuniary loss incurred is the value of the metal container. This permits radium emanation tubes and applicators to be sent on hire or loan to all parts of the United Kingdom, no security or insurance being demanded, as would be the case if radium salt apparatus were dispatched.

Mr. Hayward Pinch states that advice is freely given to medical practitioners in the treatment of disease with radium emanation apparatus, and if precise information is furnished as to the nature and extent of the disease or growth, a suitable apparatus with full instructions as to technique can usually be forwarded to any address in the British Isles within two or three days.

RADIUM THERAPY IN DISEASES OF WOMEN.

Apparatus and Technique.

In regard to the treatment by radium of diseases of women, it is stated that the amount of radium bromide, or its equivalent in some other radium salt requisite for satisfactory treatment, should be at the very least 500 milligram, which should be utilized to prepare:

1 tube of 100 mg.	= 100
2 tubes of 50 mg. each	= 100
4 tubes of 25 mg. each	= 100
2 rectangular flat varnished applicators, 3 by 2 centimetres, "full strength," each containing 60 mg.	= 120
2 rectangular flat varnished applicators, 3 by 2 centimetres, "half strength," each containing 30 mg.	= 60
1 square flat varnished applicator, 1.5 by 1.5 centimetre	= 20
Total	520 mg.

Radium emanation apparatus of the same shape, size, and activity may be used instead of radium salt apparatus where an adequate supply of emanation is available.

The set of screens should comprise:

- (1) Screens of 1 mm. silver and 2 mm. lead for the 100 mg. and 50 mg. tubes.
- (2) Screens of 1 mm. silver and 0.3 mm. platinum for the 25 mg. tubes.

The screens for the 50 and 25 mg. tubes should have the closed end pointed to facilitate their insertion into small growths and recurrent nodules.

The open end of the screens should be fitted with a screw thread to permit of the attachment of an eyeletted stopper with a silk thread, or a pliable silver wire eyelet, as occasion demands.

- (3) Screens of 0.01 mm. aluminium, 1 mm. silver, 0.1 mm. and 2 mm. lead, accurately shaped to fit the surface of the different flat varnished applicators.

No instruments other than those generally employed in gynecological work are necessary, though it is stated that it is an advantage to have all specula of the Ferguson type fitted with conical obturators. In cases of carcinoma of long standing the vaginal walls are often so infiltrated that the passage of a cylindrical speculum with abrupt edges is difficult and occasions the patient considerable pain. The use of an obturator prevents this occurrence. When the introitus vaginæ is contracted and rigid, barely permitting the insertion of the forefinger, the smallest-sized protoscope, such as used for children, is found very useful. Its passage causes but little discomfort, and it effectively illuminates the cervix, fornices, etc.

The dorsal position is the most satisfactory for the routine examination of the patient, and it usually suffices for treatment also, though in some cases the lithotomy position is essential. When introducing radium tubes into the anterior cavity, cervical canal, substance of the cervix, broad ligaments, urethra or bladder, all reasonable aseptic and antiseptic precautions should be observed, and the operator should wear rubber gloves to minimize the risk of infection.

Details of the method of application are given, and it is pointed out that patients who have received intravaginal radium treatment should be instructed to use some simple non-irritating vaginal douche daily for about four weeks after the exposure, as this will prevent the occurrence of adhesive vaginitis which sometimes ensues in susceptible subjects.

DISEASES OF THE VULVA.

In regard to the treatment of diseases of the vulva it is found that lichenification, leucoplakia, papillomata, and rodent ulcer, when they affect the vulva, clear up rapidly under radium treatment. It is an unfortunate fact, however, that patients suffering from epithelioma of the vulva rarely apply for treatment until the condition is far advanced and quite inoperable. If the lesion be small and circumscribed the result after radium therapy is usually satisfactory; in extensive flattened growths the progress of the disease may usually be arrested; in very advanced cases with deep ulceration and infiltration of the underlying tissues radium treatment may serve to heal or lessen the ulceration, alleviate the pain, and retard the progress of the disease, but it cannot do more. Sarcoma of the vulva is rarely met with; it usually appears as a rounded swelling in the substance of the labium majus, and may at first be mistaken for a fibroma. If operation is impracticable radium treatment may be tried, but the prognosis is always very grave.

DISEASES OF THE VAGINA.

Radium is of little use in the treatment of any kind of vaginal cyst, and its removal by surgical means should be recommended in preference. Polypi prove very amenable to radium treatment, and after it there is little probability of their recurrence. Primary carcinoma of the vagina is seldom met with in young women, and generally occurs some time after the establishment of the menopause. The immediate result of radium treatment is very often encouraging, but recurrence is extremely probable. Secondary carcinoma by extension from the cervix, or from the rectum, or by metastases from the body of the uterus, should be treated in the same way as the primary carcinoma of the vagina, but the prognosis is naturally not so good by reason of the existence of a primary growth elsewhere. Primary sarcoma of the vagina is extremely rare, and the two cases treated at the Institute were quite inoperable when first seen, and, in spite of temporary improvement, went on to a fatal termination.

DISEASES OF THE UTERUS.

Chronic cases of endocervicitis (cervical endometritis), which have proved refractory to all routine methods of treatment, are very often favourably influenced by radium, more especially when there is no antecedent history of gonorrhoeal or other acute pyogenic infection. It is advisable to limit the treatment to the cervical canal and surface of the cervix, and for this purpose the use of a special applicator devised by the late Dr. Louis Wickham is recommended. Patients suffering from chronic metritis, uterine fibrosis, and subinvolution have much in common. Such cases often prove most intractable, treatment by drugs alone rarely proves effective, and the cases sooner or later fall into the surgeon's hands. While curetting, amputation of the cervix, etc., may be performed with benefit, radium treatment is undoubtedly of great value, rapidly improving the patient's condition, and, if proceeded with, going on to complete cure. Cases of uterine fibroids most likely to be benefited by radium are those in which the growth is more myomatous than fibromatous in character, moderate in size, and not the subject of inflammatory or degenerate changes.

Carcinoma of the Cervix.

Mr. Hayward Pinch recommends that when dealing with carcinoma of the cervix, a clear opinion should first be formed as to the operability or otherwise of the growth, and that the cases should be grouped into three main classes: (a) Operable cases; (b) border-line cases; and (c) inoperable cases. In the first group the correct treatment should be operation, followed by a thorough course of radium irradiation. In the second group the procedure should be radiation followed by operation, provided the result of the treatment has been sufficiently definite to warrant attempts at surgical interference. In the third group radiation should be relied upon principally, but it may advantageously be supplemented by such local operations as removal of fungating portions of the growth by excision, scraping, or diathermy.

Many workers are now advocating the radium treatment of early operable cases of carcinoma of the cervix by radiation alone, and the figures they advance in support of their claim cannot be disregarded. At present, however, it would appear premature blindly to follow their lead, and early performance of Wertheim's hysterectomy in skilled hands, followed by a thorough course of radiation, still appears to be the line of action most likely to free the patient entirely from her trouble. The local and symptomatic effects of radium treatment in carcinoma of the cervix are usually very striking, and the benefit obtained not infrequently imbues the patient with a false sense of security; the symptoms which caused her so much pain and discomfort having disappeared, she imagines the disease to have been eradicated completely, and ceases to attend for examination and treatment until, after a lapse of some time, fresh symptoms develop; and when the patient is next examined the disease is found to have affected parts beyond the effective reach of radium. For this reason it is considered imperative that all patients receiving radium treatment for carcinoma of the uterus should be instructed to report at intervals not exceeding three months for a very long period of time.

From a clinical standpoint carcinoma of the cervix presents three well marked varieties: (1) the endocervical or medullary type; (2) the flattened ulcerated type; (3) the proliferative fungating type; and each variety requires a somewhat different method of treatment.

1. *The Endocervical or Medullary Type.*—These tumours originate in the mucosa of the cervical canal and form circumscribed nodular growths, unaccompanied by any external ulceration; the predominant early symptoms are an occasional slight uterine haemorrhage and a scanty vaginal discharge. Vaginal examination reveals little more than an enlarged and somewhat nodular indurated cervix. These growths sooner or later break down, ulceration and disintegration rapidly occur, and the cervix is speedily transformed into a crateriform ulcer, with its apex at the internal os; its walls are thin, hard, and extremely friable. This is by far the most malignant type of the disease; lymphatic infection takes place at an early date, and involvement of the base of the bladder, leading to the formation of a vesico-vaginal fistula, is commonly observed. In this type of growth a tube of 100 to 150 mg., screened with 1 mm. of silver, should be inserted within the cervical canal for twenty-four hours. This should be supplemented with one or more tubes of 25 mg., screened with 0.3 mm. of platinum, and inserted into the thickened cervical walls, or into the nodular infiltrations in that situation. The exposures here should be of twelve hours' duration. If definite infiltration of either or both of the broad ligaments be present, a radium tube or tubes of 50 mg. activity, screened with 1 mm. of silver, should be inserted into the infiltrated area, an exposure of twenty-four hours' duration being given there. In addition to the foregoing, a general irradiation of the pelvic cavity should be carried out by means of flat applicators containing 150 to 200 mg., screened with 2 mm. of lead, and applied immediately above the pubes, and in each iliac fossa. The exposure here should be from twenty-four to thirty hours' duration, and it is advisable slightly to move the position of the applicators from time to time, in order to avoid the possibility of producing skin vesication. The exposure may be repeated after an interval of six weeks, but not earlier.

2. *The Flattened Ulcerated Type.*—In these cases the disease manifests itself as a flattened superficial ulcer with a hard edge and a flat granular base. It much resembles a simple erosion, and is not infrequently mistaken for the same. This growth infiltrates but slowly, and tends to spread rather by a surface extension. Treatment in these cases is best carried out by means of the small 25 mg. tubes screened with 1 mm. of silver, and the most satisfactory way of doing this is to take a mould of the diseased cervix with dental modelling compound. When this is withdrawn the tubes are embedded in grooves on that portion of the mould which will come in contact with the surface of the ulcer, and the mould carrying the tubes is reinserted and maintained in accurate position by gauze packing. The exposure should be of twenty-four hours' duration, and may be repeated after the expiry of six weeks. The same procedure should be carried out with regard to the external irradiation of the pelvic cavity as indicated in the previous case.

3. *The Proliferative Fungating Type.*—This class is characterized by the so-called "cauliflower" growth, which springs from the surface of the cervix, forming an irregular fungating friable mass, which may almost completely fill the vaginal cavity. Here it is advisable, before proceeding to radium treatment, to remove as much of the growth as possible by excision, curetting, cautery, or diathermy. The remains of the cervix should then be treated by the insertion of a 100 tube, screened with 1 mm. of silver, into the cervical canal for twenty-four hours, and any outlying nodules that may have escaped the surgical procedures should be treated by the insertion of a 25 mg. tube, screened with 0.3 mm. of platinum, into their substance for twelve hours. Here, too, a general radiation of the pelvic cavity should be adopted as a matter of routine, and the exposures repeated at an interval of six weeks if necessary. The local and symptomatic benefit which usually follows the procedures indicated is usually most striking. Haemorrhage and discharge are arrested, ulceration is healed, the growth is diminished, the parametric infiltration is reduced, and

pain ameliorated. In the "border-line" cases some patients respond in such excellent fashion that within three or four weeks of the exposure the surgeon is inclined to regard as quite operable a case which before he was strongly averse to interfering with. In these cases the reduction of the infiltration and the lessening of the accompanying fibrosis are often most pronounced. This is possibly due to the fact that the peri-uterine infiltration is of a composite character, both carcinomatous and inflammatory, and the action of the radium has done much towards lessening the inflammatory effusion. It is, however, important in these "border-line" cases that too long a period of time should not be permitted to elapse between the radium treatment and the performance of hysterectomy. Three to four weeks should be the maximum. If the period of time exceed this, the fibrosis associated with the radium reaction will have taken place, and will render the removal of the uterus a more tedious and difficult operation. If one exposure in a "border-line" case fail to effect sufficient improvement to warrant operation, it is extremely improbable that further treatment will improve the outlook from a surgical standpoint, as such successive treatment inevitably produces an increased fibrosis.

Carcinoma of the Body of the Uterus.

Carcinoma of the body of the uterus is much rarer than carcinoma of the cervix, and the total number of cases seen at the Radium Institute has not exceeded 2 per cent. of all the cases of uterine cancer treated. It is more prone to occur after the establishment of the menopause, and is most generally met with in nulliparae. Hysterectomy for cancer of the body of the uterus gives much more encouraging results than cancer of the cervix, and on this account the immediate performance of this operation should strongly be urged upon patients directly the diagnosis has been established. If, however, the condition be inoperable some improvement usually follows after radium treatment, but as the symptoms of the condition are not so manifest or painful as those of carcinoma of the cervix, the result to the patient is not nearly so striking, and it is sometimes difficult, therefore, to induce them to submit to further exposures.

Prophylactic Irradiation.

The use of prophylactic irradiation in cancer of the uterus is steadily increasing, and it appears likely that before long it will be a routine procedure in all operative cases. It may be administered either three or four weeks before operation, which is advisable in all "border-line" cases; two or three days before the operation, a procedure of special value in treating cases of the proliferative fungating type; or two or three months after the major operation—this should be carried out as a routine measure in all cases in which Wertheim's hysterectomy has been performed for malignant disease, but considerable caution must be exercised in its performance.

Patients suffering from recurrence after hysterectomy often do exceedingly well, more especially if treated within a short time of the appearance of the recurrence.

DISEASES OF THE FALLOPIAN TUBES AND OVARIES.

Primary malignant disease of the Fallopian tubes is seldom diagnosed until the abdomen has been opened and an exploratory operation performed. The pathological conditions most commonly met with are either acute inflammatory conditions or cyst formations, neither of which are suitable for radium treatment. New growths of the ovary may be either cystic or solid, the former being the more frequent. Cystic tumours of any kind, however, are but little influenced by radium, and its use in such conditions is therefore of little practical value. In the late stages of papilliferous cystic disease of the ovary, when rupture of the cyst has occurred, and the peritoneum is studded with numerous secondary growths leading to the development of hydroperitonium, some transient benefit may follow exposure to radium, but such treatment must be regarded as only palliative. Ovarian fibroids are not suitable for radium treatment and should be removed surgically. The prognosis in cases of malignant disease of the ovary is most grave, and it is advised that operative procedure should always be undertaken if possible. If this be impracticable for any reason, prolonged exposures to radium may be given; by these measures some retardation of the rate of growth and amelioration of pain may be obtained, but nothing more than this can be expected.

DISEASES OF THE URETHRA AND BLADDER.

Urethral caruncle is best treated by surgical methods (cautery or excision), and radium treatment is not recommended for the condition. Primary epithelioma of the urethra is occasionally met with in elderly females, and radium treat-

ment will often produce complete disappearance of the growth, though it appears to have little influence in checking dissemination through the lymphatic system. In inoperable cases of papilloma of the bladder are often very greatly benefited by radium treatment, the growths shrinking, their vascularity being diminished, and the haematuria arrested. Inoperable cases of carcinoma of the bladder, in which the patient is tolerant of intravesical applications, may quite justifiably be submitted to radium treatment, as great improvement, sometimes going on to apparent cure, may result.

NEUROSES.

The pruritus which occurs in highly neurotic subjects, and in which no pathological lesion can be found as the exciting cause, is a most intractable condition, and radium often fails completely to bring about any relief. Even when it does prove effective, freedom from the complaint is seldom of long duration, and any undue shock or emotion will serve to bring about a return of the irritation. Patients who are approaching the menopause, and are of a definitely neurotic type, sometimes complain of severe attacks of neuralgic pain referred to the region of the ovaries, for which no adequate cause can be discovered by the most careful physical examination. Routine medical treatment often proves ineffective, and radium sometimes gives great relief, though it is probable that the results are as much psychical as physical in origin.

Mr. Hayward Pinck acknowledges his indebtedness in the compilation of his report to his colleagues, Dr. J. E. A. Lynham and Dr. Philip Gosse.

LABORATORY WORK.

Research Department.

Dr. J. C. Mottram, director of the research department, reports that during 1920 increased protection for the radium workers was instituted, and, as mentioned in the last report, evidence was being found of a return of the altered blood condition of the workers to the normal. During 1921 the evidence of this became very clear, and the details were published in *Archives of Radiology and Electrotherapy* (May, 1921, p. 368). In the case of the red cells, the polymorphs, and the haemoglobin the return to the normal was complete; only a mild lymphopenia persisted. In this paper there was also a short description of the protective devices which gave rise to this desirable result. The results of two other investigations upon the action of radium and x rays on the blood were published during the year, one in collaboration with Professor S. Russ, "Lymphopenia following exposures of rats to soft x rays, and the β rays of radium," in the *Journal of Experimental Medicine* (September, 1921, p. 271), and the other, "Observations upon the action of radium and x rays on the mononuclear leucocytes of the blood of rats," in the *Proceedings of the Royal Society of Medicine* (Pathological Section, February, 1922). During the year a new line of investigation, the basis of which was an attempt to correlate the remarkable similarity between the effects of withholding vitamin B and of exposure of animals to x rays and radium, was begun in collaboration with Drs. Cramer and Drew of the Imperial Cancer Research Fund, and as the result two papers on this subject were published in the *Lancet* (1921, vol. i, p. 563, and vol. ii, p. 1202).

Chemico-Physical Laboratory.

Mr. W. L. S. Alton, F.I.C., director of the chemico-physical laboratory, states that the number of bottles of radium solution distributed was 3,600, the output being 950 litres, and the number of emanation tubes and applicators prepared was 719. The average strength of the tubes and applicators made was higher than in the preceding year, due partly to the demand for higher dosage and to the use within the Institute of radium salt tubes containing 10 and 20 mg. of radium bromide, two of which were made and others were in preparation. The steps taken for the protection of the workers from the effects of radium have been beneficial. Increased protection was sought, and it was decided to alter the whole technique of the emanation apparatus. Protection by "distance" rather than by the use of heavy metal screens was found to be suitable, and modifications were therefore made in the department. Grants of emanation were made for lecture purposes and for research work in other institutes, and it is stated that demonstrations of the apparatus used can be given on application.

British Medical Journal.

SATURDAY, MARCH 4TH, 1922.

CANCER OF THE CERVIX UTERI.

HAVE the surgical measures adopted during the last fifteen years, and the better knowledge possessed by doctors, midwives, nurses, and the public as to the dangers of delay in cases of uterine cancer, led to a reduced mortality? There seems reason to think that during recent years, owing to anxieties, war work, and preoccupation of the minds of those concerned, the early indications of a disease so serious as uterine, and especially cervical, cancer have been overlooked or disregarded.

In the Epitome of February 4th last a short note was published on a paper by Winter in the *Zentralbl. f. Gynäk.* for December 3rd, 1921. He put this increased disregard of pre-war warnings into definite figures as regards cancer of the cervix uteri. He stated that during and since the war the percentage of patients with cervical cancer coming to his notice when the disease was in its early operable stage had markedly diminished. The actual figures he gives are 72 per cent. of inoperable cases in 1920 as compared with 34 per cent. in 1911.

In addition to neglect by the patient herself of evidences of cervical cancer, it must be remembered that the woman's usual family doctor during the war was often not available, and that to avoid consulting a stranger she might be the more inclined to postpone seeking advice till too late, fortified meanwhile by the suggestions of her friends that her losses of blood were the usual accompaniments of the menopause. The cervix is about fifteen times more frequently attacked by cancer than the body of the uterus, and cervical cancer is more rapidly fatal, owing to the lymphatic and cellular tissues round it. The operative prognosis also, for similar reasons, is much worse than when the growth is confined to the uterine body.

When in 1905, at the annual meeting of the British Medical Association at Leicester, Wertheim introduced to British gynaecological surgeons the operation known by his name, it was hoped that many valuable lives would be saved. It is, however, a question how far the extended Wertheim operation, as a substitute for vaginal hysterectomy for cervical cancer, has yet reduced the death rate when the whole mass of cases of the disease is considered. Nearly 40 or even 50 per cent. of the cases when seen by the gynaecologist are inoperable, and, except in the hands of a few, the average operation mortality has not hitherto been much under 18 or 20 per cent.; the recurrences appear to average about 75 per cent. during the first three or four years.

The statistics of the Wertheim operation in this country and abroad, both of the operation mortality and the number and dates of recurrences, vary in a remarkable manner, and seem to depend largely upon the operability rate of the operator. His optimism, his experience, and perhaps his caution and his sympathy, will, in different directions, influence his judgement in the selection of cases for operation. There is not, and at present cannot be, any fixed or standard operability rate; this creates difficulties in comparing statistics, and makes the actual and relative saving of life impossible to determine.

Radiotherapy is on its trial. Symptomatic cure of inoperable cervical cancer of the uterus, with great improvement of the general health, is claimed, but sooner

or later the growth seems to recur in outlying parts of the genital area. Irradiation in association with Wertheim's operation is, according to Mr. Hayward Pinch,¹ likely to give the best results when employed as a routine procedure two or three months after operation for early cancer, when applied in doubtfully operable cases three or four weeks before operation to reduce inflammatory infiltration, and when used a few days before the operation in fungating forms supplementing local operative procedures.

There is no doubt, however, that if the cases were seen earlier the operation mortality would be much reduced, and recurrence would take place less frequently and after a longer interval. From the point of view, therefore, of saving the lives of women who have uterine cancer, the main desideratum is to get women to seek medical advice when the first symptoms, often as they may seem to her to be trifling, are observed, for this will imply that the gynaecologist will be able earlier to consider the advisability of operation.

In 1907² Dr. Herbert Spencer read a notable paper, in the Gynaecological Section of the Annual Meeting of the British Medical Association in Exeter, on the measures to be recommended to secure the earlier recognition of uterine cancer. He showed that more women die of cancer of the uterus than of cancer of any other part of the body (19,645 such deaths in the five years 1901-1905). Of these deaths, only 30 were of women under 25, the highest mortality being between 45 and 55 years of age. There was thus an annual mortality of nearly 4,000 adult women, mostly mothers. The death rate from cancer of the uterus now, after fifteen years have passed, is no better. In 1919 the deaths from cancer of the womb in England and Wales numbered 5,162, representing 20.2 per cent. of the total deaths from cancer in women in institutions, and 17 per cent. among women in private care; only 9 of the 5,162 deaths were in women under 25 years of age. Dr. Spencer considered that the cause of this terrible mortality from uterine cancer was that valuable time was lost before the patient presented herself to the gynaecologist, owing to her ignorance of the early symptoms, and because the family practitioner sometimes delayed to examine the patient after she had consulted him, and not very infrequently patients refused to be examined or to see an expert.

A valuable discussion followed this address, and a resolution was passed requesting the Council of the British Medical Association "to appoint a committee to consider the best means of disseminating knowledge of the importance of the early recognition of uterine cancer." A committee was forthwith appointed under the chairmanship of Dr. F. J. McCann, and duly reported to the same Section at the Sheffield Meeting in 1908; two appeals were drawn up, the one to medical practitioners and the other to midwives and nurses, "in order to promote the early recognition of cancer of the womb." They were approved by the Council in April, 1909, and were published in the *BRITISH MEDICAL JOURNAL*³ and widely distributed. The appeal to medical practitioners was perhaps too elaborate, and if reissued might with advantage be simplified and shortened; but the appeal to midwives and nurses is, as was pointed out in a leading article in the same issue, "the most simple and direct document of the kind which we have seen prepared for circulation in this or any other country."⁴ The Central Midwives Board has been careful to instruct midwives to report haemorrhage during pregnancy, as, among other conditions, it may indicate cancer. We are reminded that in June, 1908, the President, Sir Francis Champneys, at the request of the Board, added

¹ *BRITISH MEDICAL JOURNAL*, this week, at p. 358.

² *BRITISH MEDICAL JOURNAL*, August 24th, 1907, p. 43.

³ May 15th, 1909, pp. 1183-50.

⁴ This appeal is reprinted in the *SUPPLEMENT* this week at p. 61.

to the other leaflets it issues one on cancer of the womb, which it was suggested might be distributed to the laity as well as to midwives. A wide distribution to women over 25 might well be adopted as regards any reissue of the briefer and more concise appeal to midwives and nurses published by the Association in 1909.

Until research enables cancer to be prevented, earlier presentation of cases of cervical cancer to the gynaecologist, with increased experience of the radical operations, especially when associated with radiotherapy, ought soon to secure a reduction in the number of deaths. This disease now annually exacts a toll of the lives of some 5,000 women, often in the prime of life and of usefulness.

THE NEW INSTITUTE OF HYGIENE.

A FEW details may now be added to what was said last week (p. 325) when announcing the gift by the Rockefeller Foundation of two million dollars (£400,000) for the establishment and equipment of an institute, or school, of hygiene in London.

The idea of establishing such an institute had been debated for some years, but no overt progress was made until a specific recommendation on the subject, in the report of the Athlone Committee on Post-Graduate Medical Education, compelled attention to the subject. That Committee was appointed by Dr. Addison, and when its report was presented to Sir Alfred Mond—who meanwhile had succeeded him as Minister of Health—he called a committee to advise him on the steps which could be taken to carry out its recommendations. In addition to the Minister, the Committee consisted of Sir George Newman, Sir Walter Fletcher, Sir H. Read, Sir J. Rose Bradford, Sir Wilmot Herringham, and Sir Cooper Perry. The recommendations of the Athlone Committee dealt with post-graduate education generally, but the goodwill displayed by the Rockefeller Foundation showed that the establishment of an Institute of Hygiene—which, as has been said, was among the recommendations of the Committee—had come within the sphere of practical politics. The generous offer of the Rockefeller Foundation was accepted by the Government, which, as Sir Alfred Mond has informed the House of Commons, undertook to provide the annual expenditure for the staff and maintenance; this, as we indicated last week, is estimated to amount to £25,000 a year. Sir Alfred Mond has appointed a small subcommittee to advise as to the choice of a site and on the plans of the new institute. It is intended that it shall be an imperial institute, prepared to receive post-graduate students in hygiene, not only from Great Britain, the Dominions and Colonies, and India, but from foreign countries also. It will therefore be necessary to provide class-rooms, lecture theatres, and research laboratories. To fulfil these conditions it will probably be considered desirable, when planning the building, to make provision for some 300 post-graduates. As we pointed out last week, London already possesses some of the elements of an Institute of Hygiene, and it is intended that the new institute shall be formed, in part at least, by entering into arrangements with existing institutions. Thus it is hoped that the London School of Tropical Medicine and Hygiene will become the Tropical Section of the Imperial Institute of Hygiene, and that the schools now giving courses for the diploma of Public Health will pool their resources within the new institute. It is intended, also, that the Lister Institute of Preventive Medicine shall be brought into intimate relation with the scheme, and it is hoped that it will undertake to provide facilities for teaching and research in certain departments.

Much importance is attached, by those most com-

petent to form an opinion, to the constitution of a governing body which will administer the affairs of the institute. Several alternatives were open. It might have been placed under the jurisdiction of the University of London had that body been a living institution; might have been placed entirely under the control of the Ministry of Health, as is the case with the somewhat similar institute at Berlin. Having regard to the number of interests concerned, however, it has, we understand, been determined to establish a special board containing representatives of the Colonial Office, the India Office, the Ministry of Health, and the Medical Research Council, and this plan will render it possible to include other bodies, should this be found desirable. It is intended, however, that the institute shall be recognized by the University of London as a school of the University and that its curriculum and certificates shall be accepted by the University for its degrees, a provision which may possibly be extended to other universities.

The scheme, so far as it has at present been worked out, is both wide and elastic, and will, it may be hoped for this reason receive the support of all the bodies concerned. It affords very great opportunities for the development of post-graduate medical education in the branches of hygiene; its benefits, though they will be limited to medical graduates and diplomates, are not to be confined to those holding British medical qualifications. On the contrary, it is hoped to make it a great international institution in which medical graduates from all countries who desire to perfect their knowledge in hygiene or to specialize in sanitary administration, will find what they need. Its laboratories, we do not doubt, will in process of time make important contributions to the advancement of bacteriology, parasitology, and statistics, in all of which there is still ample room for original work.

We do not, however, forget that the provision now to be made through the munificence of the Rockefeller Foundation is concerned with only one part of post-graduate instruction, which in London is greatly in need of better organization and larger resources. The words of Sir Clifford Allbutt seem appropriate to be recalled: "A post-graduate scheme consisting of desultory side-shows will not continue to draw serious visitors. The visitor wants not cut flowers but a nursery garden. If students are to come to study medicine in England . . . there must be something large and creative for them to come to." We can only express the hope that the country may before long be fortunate enough to witness the realization of the aspirations in this respect to which the Athlone Committee gave form if not substance.

SUPERANNUATION FUNDS AND INCOME TAX.

THERE appears to be a considerable amount of doubt as to whether payments made to a superannuation fund can be deducted in computing income tax liability, and this note is intended to state the present position of the matter. In 1903, as a result of a series of cases in the High Court, it was established that where a superannuation scheme was set up which provided *inter alia* for a return of a lump sum at death or retirement, the deductions from salaries could not be allowed for in the income tax assessment, which must be made under Schedule E on the full salary. In practice, however, the Board of Inland Revenue appears to have entered into explicit or tacit arrangements under which the allowances were made, subject, in the case of returnable deduction, to certain conditions by which the superannuation fund agreed to be bound. Extra-legal arrangements of this nature, however equitable, are undesirable, and the whole matter

¹ *Bevanmont v. Bowers* [1903], 2 O.R. 204; *Bell v. Gribble* and *Hedon v. Gribble* [1903], 1 K.B. 517.

was regularized by Section 32 of the Finance Act of 1921, which has clothed with statutory authority the recommendations of the Royal Commission on the Income Tax. Under that Act the Board of Inland Revenue received power to draw up regulations, and copies thereof can now be obtained from Somerset House, laying down in precise form the conditions under which superannuation funds will be "approved." When that approval has been given and the fund placed on the list the deductions made on payment of the salary become proper subjects for allowance for income tax purposes. It would be unprofitable to enter on any full statement as to the conditions affecting approval of a superannuation fund, but two points may be mentioned. In the first place, the 1921 Act automatically determines, as from April 6th, 1922, the operation of the previous extra-legal arrangements under which the allowances were being made, so that early action on the part of any fund affected is desirable. Secondly, the value of the allowance in these days of a 6s. income tax is not to be despised; for instance, although a new life insurance policy will carry a benefit of 3s. in the £ only, an allowance for a superannuation fund deduction operates as an "expense," reducing that portion of the assessment on which tax is being paid at the highest rate. It may, perhaps, not be out of place to warn those concerned to see that on their own assessments the application of the old arrangements has not been discontinued prematurely; where a deduction was allowed for 1920-21 it should have been given for 1921-22, whether the fund is approved under the 1921 Act or not.

PARASITES OF BACTERIA.

ELSEWHERE in this issue (page 354) will be found a review of a book in which Dr. d'Herelle of the Pasteur Institute in Paris has set out in consecutive manner the opinions he has been developing during the last four or five years with regard to the existence of parasites of bacteria. He believes such living organisms exist, and that they are widespread in nature. He proposes to call them "bacteriophages." The property filtrates of organic matter possess of inducing lysis in a culture of bacteria is commonly known as the phenomenon of d'Herelle. But it was originally described by Twort in 1915, who gave an exact description of the phenomenon; he called it a disease of bacteria, and believed it to be due to an enzyme secreted by the bacterium. It was two years later that d'Herelle announced that in the filtrate of dysentery faeces he had discovered an invisible microbe capable of producing lysis of the dysentery bacillus (Shiga). Though there has been ample confirmation of d'Herelle's experiment, yet very few investigators are prepared to accept the explanation that the changes are due to an ultramicroscopic bacterial parasite. Kabéshima has shown that the substance d'Herelle believes to be living, and has called "bacteriophage," can withstand a temperature of 70° C., and that the white powder obtained by precipitating with acetone induced the same lysis; he concluded that he was dealing with a catalytic agent which was produced by the patient as a protective mechanism against infection; that this catalyst caused micro-organisms to produce autolytic ferments, and that these ferments acted as catalysts to other bacteria, so that the lytic action was carried on from one generation to another. Bordet observed the appearance of the so-called bacteriophage in the peritoneal exudate of a guinea-pig inoculated with *B. coli* intraperitoneally. The lysis produced could be carried on from one culture to another even when the clarified culture had been killed by heat. It might seem at first sight that to explain the phenomenon as due to ferment action would require us to assume the inheritance of acquired characteristics. To this objection the reply is made that if the external stimulus produced by the original lytic agent acted by exciting an intracellular autolytic mechanism, then such a tendency to rapid autolysis might be transmitted from one generation to another even after the original exciting cause had ceased to act. D'Herelle considers that a more acceptable explanation may be given by postulating the pre-

sence of an infinitesimally small parasite of bacteria, which attacks bacteria in much the same way as the malaria plasmodium infests the red blood corpuscles and reproduces itself within them. His bacteriophage, he tells us, can only live in living bacteria; in them it multiplies rapidly, increasing its virulence meanwhile. It is a natural enemy of bacteria, illustrating the adage that "... little fleas have lesser fleas, and so *ad infinitum*." The hesitation displayed by other scientific workers in accepting the bacteriophage theory d'Herelle likens to the incredulity with which the scientific world received Pasteur's explanation that fermentation is due to the action of living cells. Pasteur convinced the world by his simple, clean, clear-cut experiments, and we are more ready to change our views than were our forefathers, and this generation does not even seek a sign. D'Herelle would have no difficulty in making us all his disciples if he produced evidence as convincing as that advanced by his great fellow countryman. The subject deserves attention because of the practical questions involved. If we are dealing with ferments secreted by cells, then such lytic agents may be valuable allies in ridding the system of bacteria. If, on the other hand, the effects are produced by living ultramicroscopic parasites, then we are in the presence of an unexplored world of life, and perhaps a form of life different from any we have yet known.

MOBILE LABORATORIES.

IN an interesting article Major A. C. H. Gray,¹ late Assistant Director of Pathology at the War Office, has given an account of the evolution of mobile laboratories and of their activities in the late war. As he took the second motor bacteriological laboratory, known as the Princess Christian Motor Laboratory, to France, he speaks out of much personal experience and supplies a number of practical details about their construction and the arrangements for carrying out the work, which entailed half the day and sometimes half the night in journeys between the field ambulances and clearing stations for the collection of specimens from suspected cases. For this purpose a bicycle and sidecar formed a most convenient conveyance, and Major Gray insists that it is much better to collect the swabs and specimens personally than to have them sent to the laboratory, for not only are they more likely to be satisfactory and capable of cultivation and examination, but it is an advantage to the bacteriologist to see the patient or contact. In some form or another the travelling laboratory was used by all the armies in the war and has come to stay; indeed, it might with advantage be employed by the civil authorities in peace, for in epidemics a mobile laboratory can by going to the patients save time and take the place of several stationary institutions. From his experience he concludes that the type of motor laboratory used by our army in France was too cumbersome and heavily equipped, and that something after the French colonial model, which was designed by Dr. Tilmont and fitted out by Messrs. Baird and Tatlock, would be more generally useful. Investigation of the history of our Army Medical Service shows that the first "mobile laboratory equipment" dates back to 1875, and consisted of a "chemical cabinet" intended for water analysis; a new and improved pattern was introduced in 1897 and used in the South African war. The first suggestion as to a field bacteriological equipment for the British Army came from Colonel Sir Robert Firth in 1909, and the use of a fitted motor mobile laboratory was advocated in 1912 by Colonel S. Lylo Cummins. But in the Russo-Japanese war (1904-5) the Russians had mobile laboratories as independent units, and the Japanese field hospitals were provided with a bacteriological equipment. In March, 1911, shortly after mobilization for manoeuvres at San Antonio, Texas, the chief surgeon of the United States Army instituted a mobile bacteriological laboratory. Major Gray, however, regards as the first real mobile laboratory that constructed in 1906 under the direction of Dr. Andrew Balfour, of the Wellcome

¹ *Guy's Hospital Reports*, 1921, lxx, 257-271.

Research Laboratories, Khartoum, and fully described in 1908 by Dr. C. M. Wenyon; it was a two-decked barge, so well equipped that it resembled a laboratory at home rather than the accommodation that might be expected on one of the upper tributaries of the Nile in a remote corner of the Sudan.

OPERATIVE TREATMENT OF MENINGITIS.

Attention is latterly being directed to the possibility of treating suppurative meningitis by operative methods. Recoveries from this disease are rare, and it is not to be wondered that determined, if as yet sporadic, efforts are being made to discover something that shall be an adjunct to recovery, if not a certain cure in itself. With our limited knowledge of the functions and workings of the cerebro-spinal fluid a rational treatment was difficult to establish. The very important work of certain American investigators, especially that of Weed when he was in Harvey Cushing's service, and later at Baltimore, together with that of Wegesforth, Dandy, and others, have furnished us with much-needed information. The direction in which these discoveries is leading us is well shown in a paper read by W. P. Eagleton before the American Otological Society.¹ A careful analysis of the literature has yielded only thirty cases of recovery from generalized suppurative meningitis. To these Eagleton adds one case of his own. Meningococcal infections are expressly debarred from this discussion. Many recorded cases he rejects because organisms were not demonstrated in the cerebro-spinal fluid. Certain of these presented a cloudy fluid with leucocytosis; others were examples of serous meningitis. Such protective reactions in the cerebro-spinal circulation often give rise to a clinical picture naturally difficult to distinguish from a true infective meningitis. Repeated punctures, local instillations of serums, and chemical solutions have led to a number of cures in this category. When there is declared and definite sowing of the cerebro-spinal fluid with organisms the chances of recovery are so small that Eagleton thinks that more radical measures might be employed to combat the usual fatal termination. He advises subarachnoid irrigation. He bores two or more holes in the frontal region, opens the dura, and inserts a cannula beneath the arachnoid. Fluid is run in, and an outlet is provided by puncture of the occipito-atlantal membrane by Ayer's well-known method, supplemented, if need be, by a lumbar puncture. The composition and temperature of the fluid used is most important. A small proportion of calcium is essential; sodium chloride alone is toxic. A modified Ringer's solution, the precise composition of which is not given, is advocated. All antiseptics when actually irrigated through the subarachnoid space appear to be highly toxic. It is true that injections of lysol and protargol have been made into the spinal theca without deleterious effect. But a distinction must be drawn between such cases and those in which an actual irrigation of the cerebral subarachnoid space has been performed. Eagleton reports three cases in which subarachnoid irrigation was done by him. In one, diplococcal meningitis followed compound fracture of the cranial base; a second was an example of streptococcal meningitis arising from a cerebral abscess, the result of a gunshot wound; the third was an instance of pneumococcal meningitis secondary to otitis. The first case recovered, the others died. Very complete clinical and pathological records are given, rendering the cases of unusual interest. The direction of irrigation was in all cases from before backwards, from frontal trephine holes to occipital puncture. Eagleton comments on the fact that the flow obtained has not been very satisfactory, especially after the first few minutes have elapsed. It occurs to us that irrigation in the opposite direction would be more promising, for Leonard Hill long ago found the same difficulty in irrigating in a caudal direction, but not in a cephalad. Eagleton now inclines to the view that the infection is *per se* the cause of death in meningitis, and that death does not

come from compression. In this view many will concur. He also is coming to believe that in cases with pneumococcal meningitis and pneumococcal infection of the blood the meningeal infection is the first thing and the blood infection secondary. He thinks therefore that subarachnoid irrigation might well be tried early in these cases and blood infection prevented. He concludes that this irrigation, which keeps open the cerebro spinal river beds, is a painless proceeding, without great danger if carefully conducted, and should be resorted to as soon as organisms are found in the cerebro-spinal fluid on lumbar puncture. As a corollary to this paper reference may be made to E. D. Davis's report² of fourteen fatal cases of otitic meningitis. Davis recommends labyrinthotomy or drainage of the posterior fossa through the internal auditory meatus. This has not sufficed to save his patients, but the conditions found after death (especially the finding of the pus over the vertex rather than in the basal cisterns) throws an interesting sidelight on Eagleton's paper.

CLEAN MILK.

To guarantee the supply of clean, wholesome milk to large towns is a problem a vast amount of labour and legislation has hitherto not availed to solve. No permanent freedom from anxiety followed the institution of the 3 per cent. standard of fat, the institution of a penalty for adulteration, and the prohibition of preservatives. The hopes founded on this legislation were quickly dispelled by the reports of bacteriologists warning us of millions of bacteria per cubic centimetre, and presence of the colon bacillus in as little as a thousandth of a cubic centimetre. These organisms may not be dangerous in themselves, but are an index of contamination, and are responsible for the rapid souring of milk. Approximately 1 per cent. of milk is lost by souring, and the losses due to this cause, combined with the irregular supplies due to the unstable character of milk, produce, it is estimated, a total loss of about one-ninth of the monetary value of the milk supply. The work done in the National Institute for Research in Dairying at Reading encourages the belief that the present unsatisfactory conditions can be easily improved. The results, Dr. Stenhouse Williams considers, justify the statement that "the best produced commercial milk can maintain a bacteriological standard of less than 10,000 bacteria per cubic centimetre for at least twenty-four hours after milking, even under the conditions of cooling and transit which exist in the country at the present time." This 10,000 colony standard is the one adopted in America; in this country more latitude is allowed, and a count of 30,000 bacteria per cubic centimetre constitutes Grade A certified milk. This standard of purity can only be maintained if attention is paid to many important details. The milk churns should be cleaned out by the persons receiving the milk; if they are sent back dirty the difficulty of cleansing them after the milk has soured is greatly increased. The churns should be properly washed out and then steamed for three minutes—a procedure which has been found to yield satisfactory bacteriological tests. Dirty milk churns are responsible for a great deal of contamination of milk. It is held that in an up-to-date farm with special milking sheds, well lighted and with abundant water supply, and if the co-operation of clean workers can be ensured, it is possible to produce milk of great purity. But Dr. Stenhouse Williams and his co-workers are to be congratulated on the convincing demonstration they have given that even on an average farm, with no special advantages as to surroundings, provided that the milker understands his business, and is provided with light, water, and steam, it is possible to produce milk of equal purity. The successful production of Grade A milk requires the co-operation of persons possessing a certain amount of technical knowledge of the precautions that should be observed in milking. The supply of this form of labour is very limited in this country at the present time. The experiments of the workers at Reading go to show that, provided the milk industry is in a

¹ "The Operative Treatment of Suppurative Infection of the Cerebro-spinal Fluid," by W. P. Eagleton, Transactions Meeting, vol. xv, Part III, p. 227, 1921.

² "Some Observations on the Early Diagnosis and Drainage of Otitic Meningitis," etc. E. D. Davis, Proc. Roy. Soc. Med., Section of Otology, February, 1922, p. 9.

position to supply Grade A milk to the consumer within twenty-four hours, no attempt need be made to keep the milk cool on the journey. Commercial milk of the bacteriological standard of Grade A will maintain its sweetness at room temperature for a period of over six days in the winter months and over three days in the summer. The two essential conditions for the supply of Grade A certified milk are: (1) the employment of intelligent milkers, working in milking sheds adequately lighted, with a good supply of water and steam; and (2) provision for the thorough cleansing and sterilization of the milk churns before they are returned to the country. There are, of course, certain other conditions into which we are not called upon to go in this place—namely, that the milkers themselves should be well housed, considerably treated, and properly paid.

THE MENTAL AFTER-CARE ASSOCIATION.

THE annual meeting of this benevolent society, which for many years has done useful social work by helping to re-establish, in ordinary conditions of working life, large numbers of poor persons convalescent or recovered after treatment in mental hospitals, was held on February 24th at Apothecaries' Hall, Blackfriars, under the presidency of Dr. W. F. H. Burgess, O.B.E., the Worshipful Master. The annual report, presented and summarized by Dr. Henry Rayner, Chairman of Council, gave a succinct account of the various activities pursued by the executive of the association in pursuance of its objects: (1) as a specialized labour bureau to find suitable employment for those fit for work; (2) as an agency for providing supplementary convalescent care in cottage homes whilst such employment is being looked for; (3) as a board of voluntary relief, visiting discharged cases and ameliorating their home conditions as far as possible; (4) reporting to asylum authorities as to such in cases about to be discharged; and (5) affording help by friendly sympathy and advice in difficulties, and so preventing relapses. No fewer than 874 cases had been considered and ministered to, wherever practicable, during the year 1921; and kindly supervision had been extended in some cases over several years. Speeches in support of the report were made by Sir Cland Schnster, K.C.B., K.C., secretary to the Lord Chancellor, who referred especially to the sympathetic devotion of the "personnel" of mental hospitals to their charge (often under trying conditions); by Lieut.-General Sir John Goodwin, K.C.B., D.G.A.M.S., who gratefully acknowledged the valuable aid rendered by Miss Vickers, the secretary, and other officers of the association, to soldiers discharged after mental and nervous troubles; 90 such cases had been dealt with during 1921. The report was adopted. Much detailed information as to the finance of the association was given, in the regretted absence through illness of the new honorary treasurer, Sir Maurice Craig, C.B.E., M.D., by Mr. C. Gabain, who pointed out that although the gross receipts for 1921 had reached the sum of £3,667 18s. 2d. (including a donation of £500 from the Maharajah Holkar of Indore) it had been necessary to trench on capital to the extent of nearly £600 to meet current expenses; and that some falling off of annual subscriptions had occurred, which it was essential to make good in order to secure stability of working. It was gratifying to note that the sum of £329 had been contributed by way of repayment by patients aided and by their friends. Speeches were also made by Mr. C. Marriott, the novelist, by Mr. Lionel Faudel-Phillips (treasurer of Bethlem Royal Hospital), by Dr. C. Hubert Bond, C.B.E. (Commissioner of the Board of Control), who expressed the Board's appreciation of the invaluable work of the association, and by Sir James Crichton-Browne, M.D., F.R.S., who remarked that a great deal was said nowadays about psycho-analysis, but what was required was psycho-synthesis, or sympathy and intelligent comprehension of "the mind shattered by disease." This valuable association, which for more than forty years has steadily but quietly pursued its beneficent course as "guide, philosopher, and friend" to thousands of sufferers from mental disorders in helping to restore them on recovery to a useful place in the workaday

world, is perhaps too little known to the profession; but full information will be gladly furnished by the energetic secretary, Miss E. D. Vickers, at the offices, Church House, Dean's Yard, Westminster, S.W.1.

THE GORDON MEMORIAL COLLEGE, KHARTOUM.

THE annual report of the Gordon Memorial College at Khartoum for 1920, which is the nineteenth, shows steady progress in all directions; it pays a tribute to the late Sir William Mather, one of its most generous supporters and an energetic member of the governing body for seventeen years. The Wellcome Research Laboratories are accommodated in the Gordon Memorial College; they are under the supervision of Major Archibald, who is maintaining the high standard set by his predecessors, Drs. Andrew Balfour and Chalmers; it contains research departments in medicine, chemistry, and entomology, the activities of which are duly set forth. Research work in the bacteriological section was interfered with by depletion of the staff and by the large amount of routine work that had to be carried out. But the director has a number of articles awaiting publication—namely, notes on urinary amoebiasis in the Sudan; on kala-azar in the Sudan; on tropical splenomegaly caused by a hitherto undescribed bacillus; on juxta-articular nodes, their etiology and pathology; and on bacilluria as a cause of pyrexias of uncertain origin in the tropics. According to the report the time when the prophets of research had to clamour for a hearing is happily past, and there is no longer any hesitation on the part of Government departments or private enterprise in appealing for assistance. Of the two possible methods of extension to meet these increased responsibilities Major Archibald advocates decentralization, by the establishment in various parts of the Sudan of local laboratories, temporary or permanent, for medical, chemical, and entomological research. This he considers preferable to the creation of new and larger laboratories at Khartoum. His recommendation has been unhesitatingly approved by the Government.

THE PENSIONS ORTHOPAEDIC HOSPITAL, SHEPHERD'S BUSH.

THE fate of the Orthopaedic Hospital of the Ministry of Pensions at Shepherd's Bush, to which we referred last week, still hangs in the balance. As will be seen in our Parliamentary column, the Minister, Mr. Macpherson, said, in answer to questions in the House of Commons on February 23rd, that he was fully prepared to reconsider the matter of the removal of the hospital, which, in his judgement, was one of the greatest triumphs of the Ministry, and which he did not wish to remove. At the same time he stated it as the opinion of his medical advisers that the work could proceed as satisfactorily as at present if the removal took place. We do not know who are the advisers in question, but we feel sure that those medical men who are most competent to judge would be unanimous in the opinion that the quality and quantity of the work would suffer if the proposed divorce of the out-patient from the in-patient department took place, and that much unnecessary waste of time and labour would be incurred by the removal of the latter to Richmond. The official mind is apt to consider that one medical practitioner is just the same as another with the same diplomas, and is equally capable of discharging any of the duties which can fall to the lot of a surgeon or physician. One F.R.C.S. in its view is the same as another, just as one Mark III rifle is the same as another. Similarly officials are apt to think that part of the work can be done at one place and part at another, just as efficiently as if the whole were kept under one roof, or to treat a matter of this kind as one of arithmetic and to ignore the value of daily personal contact and consultation between medical officers, physiotherapists, and instructors. Mr. Macpherson professed to be willing to enter into an amicable discussion with the Hammersmith guardians, but he did not take a course likely to produce a conciliatory disposition on their part when he said that he refused to be blackmailed. This was a most unfortunate

remark, and one which is likely to be deeply resented by the guardians, thereby jeopardizing the hopes of agreement. As the writer of an article in the *Morning Post* of February 27th says, "it would seem that the men who have suffered so much in the service of their country are being prejudiced because of a squabble between the Ministry and the Hamersmith guardians." If that should prove to be the case, the greatest dissatisfaction will be aroused throughout the country wherever there are crippled pensioners, and another stick will be provided with which to beat the Government candidates at the polls in the next election. No refusal to believe that a satisfactory way out of this deadlock, honourable to both parties, will not be found if the Minister will only modify his opinion of the guardians' conduct and the latter will forget their offended self-respect in the interests of the disabled pensioners.

OXFORD OPHTHALMOLOGICAL CONGRESS.

THE provisional programme for the next Oxford Ophthalmological Congress has been issued. The Congress will assemble at Keble College on the evening of Wednesday, July 5th, 1922, and the meeting will be held on July 6th and 7th, with an extension to the morning of Saturday, July 8th, should the business demand it. On Thursday, July 6th, a discussion on "The significance of retinal haemorrhages" will be opened by Dr. C. O. Hawthorne (London) and Mr. P. H. Adams (Oxford). Members intending to take part in the discussion are requested to send in their names to the Honorary Secretary, Mr. Bernard Cridland, Salisbury House, Wolverhampton. The Doane Memorial Lecture will be delivered on the morning of Friday, July 7th, by Dr. J. Burdon Cooper, the subject being "The Etiology of Cataract." The official dinner of the Congress will take place on July 6th in the Hall of Keble College. A general meeting will be held during the Congress at a time of which due notice will be given in the final programme. It is hoped that members will contribute to the success of the meeting with papers, pathological specimens, new operations, cases, or novelties of any kind. Early notification should be sent to the Honorary Secretary.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

The Insurance Bill.

THE Insurance Bill, which was introduced by Sir Alfred Mond at the beginning of the session, was, according to the frequent practice of departments of the Government, presented in "dummy," the text to be supplied afterwards and submitted for second reading. The assumption was that it was intended to follow the recommendations of the Geddes Committee and relieve the Exchequer of the balance of grant towards the medical services. The Committee suggested that an extra halfpenny a week should be contributed by the employer and the same amount by the employed in respect of each insured person, but without addition by the State, the object being to lessen the call on the Exchequer. This would have allowed also of some additional benefit at discretion of the friendly societies. According to rumour, however, negotiations are proceeding with the idea that the societies may come to an agreement to take over the balance of charge from the State, without a call for extra contributions. If this is being considered it may account for the delay in the issue of the text of the bill. On the other hand, the bill may be framed quite differently, or even withdrawn.

Pensioners: Revision of Diagnosis.

Mr. Inskip, on February 23rd, asked whether the Minister of Pensions was aware of the large number of cases which, having been classed in the first instance as attributable, were, after re-examination at a much later day, classed as only aggravated, and finally as neither attributable nor aggravated, in spite of the continuance of incapacity. Mr. Macpherson replied that it was clearly his duty to secure that entitlement to pensions had been properly conceded, and review with that object was specially necessary in connexion with a very large number of claims which, owing to the heavy pressure of work consequent on demobilization, were admitted on the report of a single medical officer. When subsequent examination by a properly constituted medical board,

followed by full and expert consideration of all the relevant circumstances, revealed an incorrect decision on entitlement, he should not be justified in neglecting to make the necessary correction. In all such cases the man was informed of the alteration and advised of his right of appeal to the Pensions Appeal Tribunal. In reply to a further question, Mr. Macpherson said that it cut both ways. Very often a man at the beginning of his demobilization was not considered to be entitled to a pension, but had since gone to the appeal tribunal and got his pension. The man always had the right of appeal to the Pensions Appeal Tribunal, which was an entirely independent body instituted at the express wish of the House of Commons, and when there was any doubt in any case he had always advised the man to appeal. This tribunal consisted of three persons. For the case of an officer there were a doctor, a lawyer, and an officer; for other ranks there were a doctor, a lawyer, and an ex-service man.

An Institute of Hygiene for London.—In reply to a question by Captain Elliot, the Minister of Health gave the particulars of the gift of two million dollars for the provision and equipment of an Institute of Hygiene in London, which we published last week (p. 325). Sir Alfred Mond said that the cost of staffing and maintaining the Institute, which the British Government had undertaken to defray, was estimated not to exceed £25,000 a year at the outset. He did not anticipate any actual charge on the votes for, say, two years. He was taking the preliminary steps towards the establishment of the Institute. The House would doubtless agree with him in heartily welcoming this evidence of common interest and co-operation between Great Britain and the United States of America in furthering education and research in preventive medicine.

Milk for Tuberculous Cases.—Mr. Hurd asked, on February 22nd, whether it was the experience of the Ministry of Health that fresh milk formed the principal part of diet in the successful treatment of tuberculosis, and whether the Minister would advise all local health authorities that they should use no substitutes for fresh milk in this or any other part of their administration. Sir A. Mond answered in the negative. He was advised that although milk might be an essential element of special diet for tuberculous persons in certain stages of the disease, or for young children, a mixed general diet was preferable in the case of adults to one consisting mainly of milk. He was further advised that certain substitutes, such as full-cream dried milk, suitably prepared for use, were as nutritious as fresh milk so long as vitamins were provided in the necessary amount in other parts of the diet.

Deaths from Starvation.—In answer to Mr. R. Richardson, on February 22nd, Sir A. Mond said that in past years special returns were made showing the number of deaths from starvation, but they were unsatisfactory and had been discontinued. If there were any deaths from starvation last year they would be recorded in the annual report of the Registrar-General.

The Spahlinger Treatment for Tuberculosis.—Mr. C. Edwards asked, on February 22nd, whether the Minister of Health was aware that many people, in all parts of the country, were interested in Mr. H. Spahlinger's professed cure for tuberculosis, and if Sir Alfred Mond would now give the result of the unofficial investigation which he told the House some time ago had been made. Sir A. Mond replied that he was aware of the interest. He understood that the unofficial investigations had been suspended until supplies of the serum were available, and that this would not be for some months to come. He should certainly assume that the result of any independent investigations by competent persons as to the efficacy of this treatment would be published.

Wound Pensions.—On inquiry by Sir F. Hall, on February 22nd, Major Barnston said that the number of men in receipt of wound pensions on December 31st, 1921, was 37,250; and the number on December 31st, 1920, was approximately the same.

The Orthopaedic Hospital at Shepherd's Bush.—Lieut.-Colonel Spender-Clay asked, on February 23rd, whether the attention of the Minister of Pensions had been called to the hardship which the contemplated removal of the Shepherd's Bush Hospital to other quarters would entail on out-patients attending the hospital; what action he proposed to take to assist such cases; and whether the saving which it was anticipated would be the result of the change would be almost entirely wiped out by the cost of removal and allowances to out-patients. A person replied that in the selection of out-patients' treatment full regard would be given to the convenience of the out-patients, and the difficulty in making the cost of the removal of the hospital and the cost of providing suitable out-patient quarters would be removed. Viscount Curzon inquired whether it was a fact that the treatment of out-patients would proceed so satisfactorily as at present if the hospital were removed. Mr. Macpherson replied that his medical staff could do it. Sir H. Foreman asked the Minister whether he would be prepared to reconsider the matter should he receive a more moderate demand from the guardians. Mr. Macpherson said he would. The desire of the Ministry had always been to maintain this hospital. Such a proposal must, however, be made at once; he could not keep the fate of these men hanging in the balance. Viscount Curzon asked whether it was a fact that the action taken by the guardians necessitated the removal of this hospital? Mr. Macpherson replied that it was, without a doubt—it was a question of rent. He pressed the guardians very hard, and had been negotiating with them for a long time, and he knew the value of the hospital. In his judgement it was one of the great assets to the Ministry of

Pensions, and he was anxious to keep it, but he refused to be blackmailed. The guardians were asking a rent which he thought was wholly unjustified.

Lip-reading Lessons.—In reply to Lord H. Cavendish-Bentley, who asked the Minister of Pensions to reconsider his decision to reduce the number of lip-reading lessons given to ex-service men suffering from deafness to twenty-five, Mr. Macpherson said that it was the definite opinion of his advisers that proficiency in lip-reading after a course of, say, twenty-five lessons, under a skilled tutor, depended entirely upon regular practice, and was in no way furthered by additional tuition. It had been ascertained that proper tuition could be given by lessons in the pensioner's spare time, under local authorities, and steps had therefore been taken to give effect to that system of instruction. While no loss of efficiency or hardship to the pensioner would result, a saving of public funds would be effected.

Pensions Temporary Medical Staff.—In answer to Mr. G. Locker-Lampson, the Minister of Pensions said that he was considering the reduction in pay of the temporary medical staff (which worked out at £972 per head) in accordance with the recommendation of the Geddes Committee.

Ministry of Health Economics.—In reply to Mr. G. Terrell, the Minister of Health said that he expected to obtain the entire saving suggested on his estimates for 1922-23 as recommended by the Geddes Committee, mainly on proposals submitted by him.

Asylum Administration Inquiry.—On further question by Mr. R. Richardson, on February 23rd, as to the refusal of the National Asylum Workers' Union to submit evidence before the Committee on Asylum Administration, Sir A. Mond said that in the first instance the union made a verbal request for representation on the Committee. When he refused this, the union declined to give evidence, and sought to justify its action on the ground that representatives of the Medical Psychological Association predominated on the Committee.

Gas Poisoning Experiments.—Sir J. Worthington-Evans, on February 23rd, informed Mr. F. Green that experiments on the results of gas poisoning were being conducted at Torton, near Salisbury. The animals employed have been rabbits, rats, and goats, and the total number used to date were twenty-six, twenty-three, and two respectively. The experiments were conducted under statutory safeguards.

Neurasthenic Pensions Cases.—In reply to Mr. Frederick Roberts, on February 27th, Major Tryon said that 18 hospitals for the treatment of neurasthenics had been established under the direct control of the Ministry of Pensions in different parts of the country, and provided accommodation for about 170 officers and 2,500 other ranks. Treatment for certified mental cases was provided by the Board of Control.

Coroners (Emergency Provisions Continuance) Bill.—Mr. Shortt, on February 27th, moved the second reading of this measure, which had come down from the Lords. Its object is to continue for the rest of the year two war-time enactments lapsing on February 28th—namely: (1) The Coroners (Emergency Powers) Bill, 1917, which temporarily reduced the maximum number of jurors to be summoned from 25 to 12 and the minimum from 12 to 7; and (2) Section 7 of the Jurors Act, 1918, which enabled coroners to hold inquests without jurors in certain cases. The whole question of coroners' juries was, Mr. Shortt reminded the House, considered by a Departmental Committee in 1910, but during the war permanent legislation could not be undertaken. The provisions now submitted for continued temporary operation had worked very well, and the whole subject was now under consideration for lasting legislation. Sir Donald Maclean, supporting the motion, observed that the findings of the Committee of 1910 included recommendations to avoid overlapping between the magistrate's inquiry and that of the coroner, so inconvenient to professional and civilian witnesses. The bill was read a second time. It had third reading on February 28th.

HOSPITAL POLICY.

I.

BY THE CHAIRMAN OF THE HOSPITALS COMMITTEE.

IN the SUPPLEMENT of last week there was an instalment of the Annual Report of the Council of the Association. It deals with hospital affairs and the organization of voluntary hospitals. The document is long; that is inevitable, for the subject is a large one. But it will prove less formidable on examination than appears at first sight, for it is in the nature of a consolidated bill. It includes the restatement of the existing policy of the British Medical Association, with such amendments as the passage of time necessitates, and new recommendations (which are clearly marked and easily recognizable) relating to the several "contributory or provident schemes" which have been put forward whereby suitable persons may provide by some method of insurance against that rainy day when hospital benefit may be needed.

The main features of the report are three: (1) A general statement of the policy of the Association on the present-day purpose of the voluntary hospitals, with a specific statement of what is meant by the voluntary principle in hospital administration. (2) A statement of the types of patients

tory schemes. (3) The reaction of the new conditions upon the honorary medical staffs.

The voluntary hospitals in their origin were charities. But with the betterment of the economic position of the vast majority of our people there are fewer persons who are fit subjects of undiluted charity. In effect the hospitals have already modified their practice to the extent of making various charges to the patients, which the patients view as payment, in part at least, for whatever the hospital affords them, whether treatment by a doctor, the supply of medicines, or nursing or maintenance when in hospital. Some would argue that the change has destroyed the voluntary principle, but the Association puts its finger on the voluntary method of administration as the factor that gives the voluntary hospitals their outstanding advantage. There is no quarrel with State hospitals maintained under statutory authority and rule; but it is claimed that private enterprise in hospitals, as seen in the voluntary hospitals, presents such advantages to the public, medical science, and the medical profession that it should be maintained, even though this be accompanied by modifications in practice necessitated by altered conditions.

The charitable side of these hospitals must be continued just in so far as there is need for it and so far as gratuitous contributions permit, and for the indigent patients the hospital staff should continue their free services. But it is recognized that the voluntary hospitals should be developed so as to provide accommodation for paying patients, so that the benefits of these institutions may be available for those who cannot secure proper treatment elsewhere. The working out of this position is seen in the recommendations regarding contributory schemes. Schemes have been submitted to the Association for approval. They were originated by medical men, and these are desirous that the general body of their colleagues should approve them. The reply is that definite schemes should not be approved in our present limited knowledge, but certain standards are submitted which these schemes should reach to render them safe and effective. A leading condition is that the hospitals themselves should not take insurance risk; contributors should bargain with some independent body, which in its turn would pay the tariff dues chargeable to its members by the hospital when hospital benefit is given. Only by some such plan can the hospital maintain its independence in determining which is and which is not a fit case for hospital treatment, and avoid the risk of charging some part of the costs of these patients to the purely charitable funds of the institution.

Another important point arises in connexion with consultations and specialist treatment. Some of the contributory schemes put forward would tend, if successful, to bring all this work into the hospital out-patients' department, and possibly limit the field of choice of practitioner unduly, to the detriment of medical progress. The report recommends that any such arrangement should provide for these services to be rendered at the homes of the practitioners wherever possible.

The introduction of paying patients to voluntary hospitals, whether tariff patients through a contributory scheme or private patients in nursing home annexes, has the inevitable corollary that members of the staffs attending these patients must receive some remuneration for the work they do. With private patients this should be a matter of private arrangement between doctor and patient. In the case of tariff patients the recommendation is for the transfer of a percentage of the charges to the staff fund, after the manner which proved so efficient in arrangements for the treatment of State patients during the war.

Finally, the independent management of the voluntary hospitals must be safeguarded. It must not fall under the control of one set of supporters or contributors. Each interest should be represented, and none be in a majority. Otherwise there will be a limitation of outlook of governing bodies, to the detriment of the hospitals and of medicine.

The report is referred to the Divisions of the Association. But I would also urge every member of the staff of a voluntary hospital to give this report his personal thought, and to secure a joint consideration of it by his colleagues, and possibly with the members of his hospital board. The views of the hospital staffs will be required at no distant date. The King Edward's Fund for London has for the moment deferred any decision on the institution of a contributory scheme, but recommends that steps should be taken to ascertain the considered opinion of the medical profession in

into practice would ultimately involve. Also the Council of the Association is arranging to hold a conference of the staffs of voluntary hospitals on Wednesday, March 22nd, to consider this report.

II.

BY A COUNTRY PRACTITIONER.

ALL country practitioners reading in last week's SUPPLEMENT to the BRITISH MEDICAL JOURNAL the report of Council on the organization of voluntary hospitals must realize its importance, no less to themselves than to their colleagues in town. Their more immediate concern is with the cottage or local hospitals; but the policy of the central hospital is of equal if less direct consequence to them, so that they may quite pertinently express their views on the whole policy set out in the report.

It must be realized that this report will eventually be considered by the public; it is doubtful whether it will accept the definition of the voluntary system of hospitals as being essentially the voluntary or independent management. The great majority of laymen would say that the essential principle was the voluntary support; this is the definition cited in *Burdett*; it is the official explanation given by the Voluntary Hospitals Commission; it is the superscription on many a hospital building. Why not include it in our own official statement?—always remembering that a voluntary contribution is not necessarily a charitable contribution; in fact, with the larger proportion of voluntary contributions there is an implied benefit to the donor—admission tickets or even treatment, patronage, control.

No doubt this system does not necessarily involve the gratuitous services of the medical staff, but by long custom and association this has become an accepted principle in the conduct of our voluntary hospitals, and many members of the honorary staff, as well as the public, will require to be satisfied as to the reasons for the proposed change of policy. It is clearly set out in paragraph 2 that medical treatment has been given gratuitously and willingly to those unable to pay for it, but it might with advantage be made clear that the proportion of patients for whom no payment for treatment can be provided has of late years grown very much smaller. There are other reasons why it has become proper and advisable to remunerate the medical staff. Voluntary hospitals were originally founded to secure treatment for the poor; they now exist to provide institutional treatment for all cases of the community that may require it. They exist also for research work, for the advancement of medical science, and the continued instruction of medical practitioners—all this for the benefit of the public. Some also are necessary for the teaching of medical students. The hospital is the place where medical men can meet together and work together to initiate and to perfect not only means of treatment but means of prevention for the benefit of the whole community. This being accepted it is obvious that the medical men doing the work of the hospitals have a considerable claim to some sort of remuneration, also that it is to the interests of the public that as many keen and efficient practitioners as possible should take part in the work. It is not expected, it would not be practicable, to provide payment that might be considered a full reward for the work done, but it should be some recompense for time and services given. As it is advisable to encourage the younger members of the profession to take an active part in this work it is important that they at any rate should have some assistance; otherwise the result must be that they cannot afford to do the work at all or if they do, they have to devote so much time and thought to the struggle for existence that there is not enough left for the scientific work that they would probably prefer. It is only by throwing open more hospital appointments to younger men, by making the term of office shorter, and by offering some payment for the work, that it will, under the altered circumstances of these days, be possible to attract to the service, to select and to keep there the keenest and ablest men in the profession. What is now happening only too often is that the brains and the work of many an enthusiast are lost to the hospitals. It is being found increasingly difficult to get men to fill many of the junior posts in some of our large hospitals; they cannot afford it, and prefer to take other paid work.

It is quite possible, even probable, that the senior members of the staff—those who have succeeded in practice—will be willing, will prefer to give their services gratuitously; at any

rate to a large extent; it is very necessary to retain their services, but the work they do need not be so exacting.

It should be made clear that acceptance of payment does not necessarily involve either State or lay control; it does not mean now or later on a State service. Many of the public and of the profession think, probably rightly, that men will do for love of science and humanity what they will not attempt for a State service. But to assume that work will not be so keen, or the hospital spirit not so strong, because the staff receive a monetary acknowledgement of their work, is not logical. The utmost keenness, the best hospital spirit, the sincerest love of humanity, will not alone enable a man to live. Some men fear that by accepting payment they will lose prestige and influence with the public and the profession; but surely these do not come because the work is gratuitous, but because of the experience and skill that follows the work well done.

Whether the proposal to form a staff fund by deducting a percentage of certain payments is the best, is open to question; it is doubtful whether it would, as things are, be of much benefit to practitioners attending cottage hospitals, but this is not the place to discuss it.

It is quite necessary, as stated in the report, that the medical profession should have a share in the management of the hospitals, but it would, I think, be a mistaken policy to press the recognition by the authorities concerned of the suggested Advisory Medical Committees; these should of course be formed, but in the hope that the authorities would of their own accord recognize and consult; unless the consultation is voluntary it is not likely to be of much avail.

At the moment, though cottage hospitals are just as necessary in big towns as in country districts, the proposals in the report as they affect these institutions are particularly interesting to country practitioners—in the first place, because it is quite obvious that if the hospitals are put on a better business footing, as they would be, their capacity and the scope of the work that could be done in them would be considerably increased. Work here should be part of the daily routine of the practitioner; it is here that he can do most satisfactorily much of his work; here that he can conduct much valuable clinical research, that he can find opportunity for his skill, his imagination, his professional and scientific ambition; here he can collaborate with his fellow practitioners and specialists, with mutual advantage, and benefit to his patients; here he can admit and hope to treat effectively so many cases that he now perforce too often can only look after in their ill-suited homes; here can be examined and observed cases that otherwise must remain enigmas; it is here, in fine, that he can, better than anywhere else, bring pleasure to his practice, skill to himself, and health to his patients. But his opportunities are limited for want of beds and equipment and for want of time—for want of time because he has himself a family to support, because he is human and wants to make not only cures and discoveries but money too, and this he cannot do if he sends patients, who are paying him at home, into hospital and cures them there without reward and in half the time. It may be said that he has the reward of gratitude and satisfaction for work well done, and that the consequent reputation will bring him more practice later on. But this will not feed him now, and as to the work later on, the hope and object of those who believe in the advantage of hospital treatment is that it will become available for a constantly increasing proportion of people, in which case remunerative domiciliary practice will correspondingly decrease.

In this connexion some objection may be raised to the classification of patients in paragraph 19. Private patients are described as "those who pay for special accommodation and who arrange for medical treatment fees independently of the hospital." In some cottage hospitals there are already patients who are willing to pay the cost of their maintenance, without special accommodation, and who pay the doctor for treatment independently of the hospital.

THE tenth International Congress of Otolaryngology will be held at the Paris Faculty of Medicine from July 19th to 22nd, under the presidency of Professor Seibican. The following subjects will be discussed: (1) Cerebellar abscess, (2) otogenic meningitis, (3) the value of functional tests of the vestibular apparatus, (4) syphilis of the ear, (5) x-ray and radium treatment of cancer of the larynx. The titles and brief abstracts of papers should be sent to the general secretary, Dr. A. Hautant, 23, Rue Marbeuf, Paris, before April 8th. The subscription of 100 francs should be paid to the treasurer, Dr. Georges Laurens, 4, Avenue Hoche, Paris.

England and Wales.

MANCHESTER ROYAL INFIRMARY.

According to the last report of the Manchester Royal Infirmary the year 1921 surpassed all previous records in the number of annual subscriptions, and there has been a further substantial increase in the contributions of in-patients and out-patients. Expenditure, however, exceeded income by £23,255, but it is suggested that there are indications that the high-water mark of the prices of commodities has now been passed. Owing to its association with the Medical School of Manchester University the Infirmary is involved in a greater expenditure than hospitals to which no medical school is attached, and it is noted further that the thirteen teaching hospitals are responsible for no less than 50 per cent. of the total deficit incurred by provincial hospitals. Lord Cavo's Committee, when investigating the financial condition of the voluntary hospitals, recognized that hospitals with medical schools must necessarily be under greater expense than other hospitals, and it is hoped that through the representations of this Commission a grant in aid of teaching will be made by the Government. The Board had long recognized that the amounts contributed to the Infirmary and the local hospitals by employers of industrial undertakings and workers of all grades had not been in proportion to the vast number of workers employed in the district served by the hospitals; it is of the opinion, therefore, that the time has now come for setting up machinery necessary to obtain adequate contributions from these sources, and thus to restore something like equality between income and expenditure in the hospital accounts. Representatives of the hospitals have been appointed to deal with this important matter, and a scheme has been formulated which will be put forward during the present month. While the Hospital Saturday Funds at Birmingham and Newcastle contribute £30,000 and £28,000 respectively to the hospitals, that of Manchester and Salford, with a population larger than Birmingham, and four times larger than Newcastle, contributes only £5,548. The necessity for increased accommodation for nurses, the extension of the x-ray and electrical department and the aural department, referred to in the last report, involving additional expenditure estimated at over £200,000, continues to be a serious problem. During the year 11,252 in-patients were treated, and the out-patients and accident cases treated at the Infirmary and the Central Branch numbered 47,164; the number of persons treated in all departments, inclusive of the Barnes Convalescent Hospital, totalled 59,902. It is recorded that the honorary radiologist received an offer from an anonymous donor of sufficient funds to enable research to be carried out on the method of intensive x-ray treatment of cancer. A scheme has been drawn up and a research scholarship in intensive radiotherapy for the treatment of cancer was instituted. Apart from research on cancer carried out in other departments, the work of the Cancer Research Laboratory in the Infirmary was continued during the past year.

CLINICAL ASSISTANTS AT LONDON MENTAL HOSPITALS.

The London County Council nearly two years ago fixed at eight the normal establishment of assistant medical officers at mental hospitals which normally accommodate 2,000 patients or more, and at the same time suggested that it might be possible to fill the position of eighth assistant medical officer by the appointment of a qualified clinical assistant. The proposal to appoint clinical assistants was based on the assumption that general practitioners and others would welcome an opportunity to obtain experience in the diagnosis and treatment of mental disease, and would be satisfied with remuneration sufficient to cover their expenditure on board and lodging. Applications were accordingly invited for the position at a salary of £200 a year, without emoluments, but this has not attracted candidates, and after further consideration it is now proposed to invite applications at a higher rate of remuneration. The position of eighth assistant medical officer in the London county mental hospital service is therefore to be filled by the appointment at each hospital of a duly qualified clinical assistant, at a salary of £400 (on present economic conditions), without emoluments. The appointments are to be held for a period of six months, and favourable consideration is to be given to applications from women candidates.

Scotland.

CLINICAL MEETING OF THE EDINBURGH BRANCH.

The annual clinical meeting of the Edinburgh Branch of the British Medical Association was held in the Edinburgh Royal Infirmary on February 17th, and in spite of unusual difficulties, caused particularly by the influenza epidemic, proved very successful. In the morning a number of demonstrations, which had been arranged by Dr. John Eason, was held in the different departments of the Royal Infirmary. These included a short demonstration on physical methods and appliances by Dr. A. D. Webster, and a demonstration on venereal diseases by Mr. David Lees. Dr. Chalmers Watson gave a clinical and laboratory demonstration on alimentary sepsis, including x-ray examination, and the results of naked-eye, microscopic, and bacteriological examination of the urine and stools. A series of cases was shown, including one in which a loop of duodenum was removed at operation by Mr. Wilkie, with the results of the bacteriological examination of its contents. Dr. Dawson Turner gave a demonstration on radium and its application in the treatment of disease. A demonstration of chemical tests for renal function, including estimations of blood urea and non-protein nitrogen, urinary urea concentration, phenolsulphonephthalein excretion, and kidney fixation tests, by Dr. John D. Comrie, Mr. C. R. Harrington, and Dr. Malcolm Smith, was given in the Biochemical Laboratory, where Dr. Davies also gave a demonstration of the basal metabolic rate in cases of disturbed thyroid function. Professor G. Lovell Gulland gave a lantern demonstration of x-ray photographs of normal and diseased organs. Later in the afternoon a surgical and medical demonstration was held in the large surgical theatre of the Infirmary, where cases were shown by Sir Harold Stiles (including, with Dr. Edwin Bramwell, a case shown eight weeks after laparotomy for the removal of an endothelioma of the pia arachnoid opposite the seventh dorsal spinal segment), Sir David Wallace, Professor F. D. Boyd, Dr. H. Rainy, Mr. J. W. Struthers, Mr. D. P. D. Wilkie, and others. A pathological museum was arranged in the Pathological Department of the Royal Infirmary, and was open throughout the day; a large number of interesting pathological specimens was exhibited, in addition to various splints and appliances. In the evening a dinner took place at the Caledonian Hotel, which was a very enjoyable function after the heavy day. Dr. William Stewart, President of the Branch, was in the chair, and after the loyal toasts had been duly honoured, the health of the British Medical Association was proposed by Dr. C. E. Douglas, and responded to by Dr. Drever. Dr. John Keay proposed the health of the guests, which was responded to by Dr. R. C. Buist of Dundee and the senior president of the Royal Medical Society. The health of the President was proposed by Mr. D. P. D. Wilkie, and after the President's reply the meeting closed with the singing of "An'd lang syne." The secretaries, Dr. John Stevens and Dr. John Eason, are to be congratulated on the success of the annual clinical meeting.

THE ROYAL EDINBURGH MENTAL HOSPITAL.

Professor G. M. Robertson's annual report of the Royal Edinburgh Mental Hospital is always interesting, often suggestive, and sometimes inspiring; in the present instance it is all three. In last year's report (*Journal*, March 12th, 1921, p. 400) emphasis was laid on the part played by alcohol in the supply of patients for this and similar mental hospitals; this year the prevailing stress is rather placed upon "voluntary treatment." The number of patients admitted to the two departments (Craig House and West House) during 1921 was 506, compared with 523 in 1920; in these two years, therefore, 1,029 patients were admitted, and the average population of the hospital during that time was 1,018. Dr. Robertson rightly draws attention to these rather extraordinary figures, and he claims that no mental hospital in the kingdom has ever had so high an admission rate in proportion to its permanent population. The proportion of inmates suffering from acute illness is higher than in ordinary mental hospitals, and that of chronic patients who are in good health and able-bodied is much smaller. The explanation is that the institution is still doing war work, Glasgow not having yet been reopened for its ordinary uses. To provide for the new admission

about a fourth part (133) were transferred to other asylums before they had been long enough under treatment to expect recovery. The statistics of recoveries and deaths could not therefore be fairly compared with those of other hospitals doing normal work. The recoveries were 106 and the deaths 159.

A somewhat unusual occurrence was the appearance of pellagra, there being four cases (all in females), of whom three proved fatal. Dr. Robertson points out that this disease, common enough in Italy and sunnier climes, was not known to exist in Great Britain until a girl suffering from it was discovered in West House in 1911; since then other cases had been found in different parts of the country. Diseased maize, the alleged cause in other countries, could not be held responsible here, as none of the four patients had ever tasted maize, and it seemed clear also that they had not eaten chickens fed on that foodstuff. Dr. Robertson is inclined to attribute the malady to some form of food deficiency. The distinctive eruption is developed usually under the influence of sunlight, and, since the Morningside patients lie out so much in verandahs, it is possible that in them diagnosis is thus made easier, especially in sunny summers such as that of 1921. Apparently, therefore, there may be other cases of pellagra waiting the advent of sunshine to be recognized in other asylums and among the general population.

The voluntary treatment of insanity is one of the most hopeful parts of the work at Morningside. Exactly one-half (fifty) of the patients admitted to Craig House (the department for private patients) in 1921 entered voluntarily. These persons belonged to the educated classes and were able to pay the higher rates of board in Craig House; but ever since the introduction of an excellent provision into the 1913 Act the practice has been growing, and its extension to other classes may be confidently looked for. The new provision in 1913 was that whereby a simple written application to the medical superintendent alone enabled a patient at once to be admitted to the hospital. The fact that this plan of entering an asylum is so largely taken advantage of shows the degree of confidence that the general public of the better classes have in the administration and curative value of such institutions as the Royal Mental Hospital. Another conclusion surely follows—namely, that at least one-half of those suffering from mental disorder have, at any rate in the earlier stages of their illness, some insight into their condition or consciousness that they are not well in mind. Advantages of many kinds accrue from voluntary treatment. It can be begun earlier, and therefore with more hope; when a certificate is needed the disease must necessarily be more unmistakable and further advanced. The presence of the voluntary patients makes for ease in efficient administration and, above all, it gives confidence among the general public that all is well within the institution, for it does away with the so-called "stigma" of certification. In order, however, that this benefit may be extended to the poor, a change requires to be made. At present the poor are debarred because the Government gives a grant-in-aid to the parish councils for the maintenance of certified lunatics, but nothing for the upkeep of voluntary patients. Professor Robertson is able to record a case in which this anomaly led to hardship. A private mental nurse came from the country, accompanied by a friend, with the express object of putting herself voluntarily under treatment in West House. She was suffering from melancholia, and was admitted; but the next day she was certified as a lunatic and detained under an order granted by the sheriff solely that the parish of her settlement in paying for her board might obtain the assistance of the Government grant-in-aid, which is given for certified lunatics but not for voluntary patients. This occurrence brings back to Dr. Robertson's memory Samuel Butler's satire, *Everhoun*, in which a man was accused of pulmonary consumption, was tried, found guilty, and was sentenced to imprisonment, with hard labour, "for the rest of his miserable existence." It is obvious that in this and in other directions it would be well if legislation were introduced facilitating the coming of patients in early stages of mental disorders for efficient treatment, not only in mental hospitals, but also in nursing homes and hostels. The managers of the Royal Edinburgh Mental Hospital have opened two nursing homes, and will soon open a third, for the purpose of early treatment, and they have also acquired a country house for convalescent patients; in this way accommodation for fifty patients has been secured. These homes are not mental hospitals, they

are not a part of Craig House, they do not come under the provision of the Lunacy Acts, nor are they supervised by the General Board of Control, but, being the property of the corporation, they are under the care of managers well qualified to deal wisely and well with the inmates. But again, such nursing homes are for the better-off classes, and the question arises about the poor who should have the benefit of early treatment also. Professor Robertson thinks that a way will be found through the co-operation of four bodies—the Edinburgh Royal Infirmary, the parish council, the University, and the Royal Mental Hospital; by this quadruple alliance it may be possible to establish an early treatment hospital, centre, or clinic, and with the reopening of Bangour for its pre-war work West House at Morningside would be able to afford the necessary accommodation. Dr. Robertson earns the thanks of the profession for his practical realization of the truth that prevention is better than cure and that early treatment is better than late.

GLASGOW MEDICAL LUNCH CLUB.

The weekly meeting of this club, held on February 23rd, was rendered especially interesting by the presence, as guest of honour, of Sir Donald MacAlister, K.C.B., Principal of Glasgow University and Chairman of the General Medical Council. From his long experience of the work of the Council, extending over a period of thirty-three years, during half of which he has been president, Sir Donald gave an interesting account of its functions and influence. The Council, he said, was neither a professional parliament nor a union for the protection of professional interests. The declared object of Parliament when, in 1858, the Council was first constituted was simply the interest of the general public, and not the welfare of medical men or of professional corporations. By the preamble of the Act it was determined that persons seeking medical aid were to be enabled to distinguish "qualified" from "unqualified" practitioners. Machinery was set up whereby the "qualified" were hall-marked, but the public were free then, as now, to employ the "unqualified," should they so desire. Except for some limitations the unqualified were left untouched by the law. The qualified, however, having received his legal status and official recognition, became subject to a new central control, both educational and disciplinary, from which control the unqualified was exempt. Although in other countries and British Dominions the law restricted practice to the qualified, legislation to the same effect with regard to medicine and surgery was not very probable in this country in the near future. Parliament would go so far as to distinguish the trained from the untrained, but the public were left to make their own choice at their own risk. All the Council's power and work, apart from a few subsidiary matters, had reference to the two statutory functions of education and registration. Though its positive statutory powers in both these fields seemed meagre it had gradually but surely developed an influence which was real and potent for good. They worked by the exercise of moral rather than legal pressure, and this good influence was due, he thought, to three factors: (1) the constitution of the Council itself; (2) the loyalty of the teaching and examining bodies; and (3) the publicity of the Council's proceedings. The acknowledged weight of educational influence wielded by the Council in moulding the content and standard of professional training had been reached not by compulsory rules and regulations but by recommendations made and accepted by common consent. This moulding process was still going on, and at present some twelve committees, representative of all branches of the profession, were considering the revision of the present curriculum. The final result when approved by the Council would go forth as a recommendation to medical schools and licensing bodies, and he had not the slightest doubt that, as in the past, these would follow the lead of the Council for the sake of the well-being of the profession which was their special trust.

GLASGOW HEALTH VISITORS' ASSOCIATION.

At the annual meeting of the Glasgow Infant Health Visitors' Association the chairman, Bailie Angus McDougall, said that it now had seventeen branches, three or four of which worked in or round the original Cowcaddens area; associated with these branches there were now between 300 and 400 voluntary visitors; the Association during the past year had kept under supervision altogether some 3,770 infants. During the same period the corporation had appointed four lady medical officers

to devote their whole time to child welfare work, with a nursing staff of twenty. The corporation had also taken over and expanded the day nursery services formerly carried on by the Day Nurseries Association. The vital statistics contained in the report afforded a measure of the progress which had been made.

Ireland.

THE LATE DR. J. A. HANRAHAN.

DR. WM. DOOLIN, honorary secretary Leinster Branch, writes: Some months ago (April 9th, 1921, p. 841) you very kindly published an appeal on behalf of the widow of the late Dr. Hanrahan. As the bulk of the subscriptions we received came from members of the Association, through your publication, I enclose the list of subscribers with the amount contributed by each:

- £10.—Dr. H. Meade, Captain P. J. Ryan, R.A.M.C., Dr. J. M. O'Connor.
 £5.—Drs. W. M. Crofton, H. C. Venis.
 £3 3s.—Drs. H. Barniville, W. Doolin, W. M. Falkiner, V. Tighe, E. P. McLaughlin.
 £2 2s.—Mrs. Cantwell, Drs. M. Gumel, P. Foote, Lieut.-Colonel T. Murphy, I.M.S., Dr. C. J. Macanley.
 £2.—Drs. E. Murphy, A. L. Nielan.
 £1 1s.—Drs. S. S. Simmons, G. H. Nelly, L. T. Hardy.
 £1.—Mrs. K. O'Connor, Drs. R. O'Connor, H. P. O'Sullivan, S. H. Taylor.
 10s. 6d.—Dr. W. D. O'Kelly.
 10s.—Mr. J. Doyle, Dr. W. J. Dewar.
 Per Dr. T. Dillon:
 £1 10s.—Some Students at Vincent's Hospital.
 Per Dr. M. C. McGrath:
 £1.—Drs. F. W. Kennedy, J. Devane, W. A. Fogarty, M. C. McGrath.
 10s.—Drs. J. Roberts, J. Massy, Malone, P. F. Graham, W. J. O'Sullivan, A. Humphries.
 Total amount received, £47 19s.

Correspondence.

A DIPLOMA IN TUBERCULOSIS.

SIR,—In connexion with the letter of my friend, Professor Lyle Cummins, in last week's JOURNAL, and your comments on the proposal for a diploma in tuberculosis, will you allow me to indicate briefly the existing arrangements and outlook of the University of Edinburgh?

Tuberculosis is now included in the curriculum for the degrees of Bachelor of Medicine and Bachelor of Surgery, and candidates for the Final Examination must present evidence of having attended a course of not less than thirty meetings.

The University course for undergraduates deals with tuberculosis in the widest sense, and more particularly with its practical aspects. The course, which is conducted by the professor and several assistants, includes a survey of the etiology, pathology, diagnosis, prophylaxis, and treatment of all forms of tuberculosis, special attention being directed to the clinical side. Opportunities for practical work are afforded both in the classroom and at various tuberculosis institutions. The subject is included in the Final Examination, at which board the professor of tuberculosis sits, along with the professor of medicine and the extern examiner.

The curriculum for the Diploma in Public Health, recently instituted by the University, extends over an entire academic year, and includes, in addition to the more general subjects of public health (chemistry, bacteriology, parasitology, administrative duties, etc.), special training in tuberculosis, clinical and administrative, as also in venereal diseases. The medical inspection of school children, and child welfare. The General Medical Council is at the present time considering the advisability of altering the conditions and standard the curriculum for the Diploma in Public Health. In view of the extending scope of the health service of the country it is eminently desirable that all officers attached to the service should have practical training in those subjects.

From men who intend to devote themselves more specially to tuberculosis, which is now a recognized division of the health service, more may well be required—and what applies to tuberculosis is no less applicable to the other medicalized departments. In the interests of those who have attained advancement to higher posts in those departments, it seems reasonable that some official credential should be available in respect of higher study and proficiency in the given subject. This might readily be afforded by attachment to the general Diploma in Public Health of an additional certificate to the effect that such special proficiency

had been attained. The extra statement would be a matter for the examining body before which the candidate appeared.

The practical result would be that, while some candidates remained content with the possession of a general Diploma in Public Health, others would prefer to have the diploma with honours, pointing to special proficiency in one or other department. The proposal obviates what most of us feel to be undesirable—namely, the multiplication of special diplomas in limited departments of medicine.—I am, etc.,

University of Edinburgh, Feb. 25th.

R. W. PHILLIP.

THE RECOGNITION OF AORTIC INCOMPETENCE.

SIR,—I am obliged by the three courteous notes of comment on my paper on the recognition of aortic incompetence. Unlike Dr. Gordon, I never use a binaural stethoscope except occasionally for children and for getting at stout patients in awkward positions in the middle of a full-sized bed; with the form of wooden stethoscope which I use I can hear as much as, if not more than, I can with direct auscultation.

The views of my old teacher, Dr. Graham Steel, on the evidence of aortic incompetence which is to be gained by inspection are as sound and instructive as are all the writings of such an observant clinician as he is, but the passage quoted refers to cases in which the incompetence was advanced, and my concern was with the earliest appearance of the disease, as, indeed it is Dr. Heatherley's too. I agree with Dr. Heatherley on the effect of change of posture on the audibility of some aortic diastolic murmurs and with his other remarks, some of which I would have added to my paper had I not been anxious to save space.

My answer to Dr. Broomhead's question, "Is it not an established fact that in order to make a diagnosis of aortic stenosis three essentials are necessary: (1) a thrill over the aortic area, (2) enlargement of the left ventricle, (3) definite signs of aortic regurgitation?" is that (1) a thrill only occurs in a proportion of cases of aortic stenosis; (2) enlargement of the left ventricle does occur, and this varies with the degree of stenosis; (3) a diastolic murmur of aortic incompetence is not always present in aortic stenosis. A systolic bruit heard at the base does not justify a diagnosis of aortic stenosis or obstruction (the difference between these two conditions is one of degree only), unless the murmur is heard also over the carotid artery without pressure from the stethoscope. But even in these conditions the murmur may occasionally be a posture murmur and arise from pressure on the subclavian artery from muscle or collar-bone, or even cervical rib, as I have described in my book on *Heart Disease*. Such a posture murmur was the cause of some rejections of army recruits during the war which came under my notice.

I am obliged to Dr. Broomhead for his interesting figures on the incidence of syphilis in heart disease.—I am, etc.,

Manchester, Feb. 25th.

E. M. BROCKBANK.

HOLLOW VISCERA AND VESSELS: CURVATURE AND PRESSURE.

SIR,—In your issue of February 18th Dr. Cranston Walker in an excellent article draws attention to some interesting and highly important applications of Lagrange's tension and pressure theorem to the human body. This subject deserves careful study.

In the year 1892 I read a paper before the Royal Academy of Medicine in Ireland on quite similar lines. It may be found in the *Transactions* for that year, and also in the *Journal of Anatomy and Physiology*, vol. xxvi. I only dealt with the statics, but there were one or two points brought out in my paper that I think are worth mention.

The first was that the theorem gives a perfect explanation of the varying thicknesses of the heart wall, and of the fact that when the heart ruptures it rarely does so at its thinnest part.

The second and more practical one was that it affords the true explanation why allowing the liquor amnii to escape precipitates labour; not, as used to be held, and sometimes still is, on account of foetal movements stimulating the uterine wall to greater effort, but owing to decrease in the radius of curvature of the viscus enabling the same tension in the wall to give rise to a higher pressure on the contents.

It is safe to say that there is no single point in physics of such wide application to the human mechanism, nor one better worth understanding by those who have to treat surgical, or indeed medical, complaints. To give only one

example, but an important one, it affords the true explanation of the inability of dilated intestines to empty themselves of their contents.—I am, etc.,

Dublin, Feb. 20th.

ROBERT H. WOODS.

SIR,—I have read with much interest the extremely valuable paper on the above subject in your issue of February 18th by Dr. Crauston Walker, and I sincerely wish that he would further develop his work on many practical lines which lie open to his investigation. A clear knowledge of the principles which he has enunciated as applied to the circulation might save much useless and injurious medication to which patients are subjected by the modern cardiologist. His physics strongly support the views expressed by Dr. J. R. Gillespie recently in your columns.

I shall only give a couple of illustrations to show the importance of his facts as applied to the circulation:

1. If the body be inverted, the static pressure in the carotids is increased, but those vessels at once contract down to about half their previous size, and with the diminution in the radius of curvature the tension is increased, and the greater internal pressure converts the energy of the blood into velocity, and thus the cerebral capillaries are saved from the great static pressure to which otherwise they would be subjected.

2. When a great volume of blood is thrown out of the left ventricle at each systole, and there is great disparity between the diastolic and systolic pressures, we get longitudinal straining of the arch of the aorta, and an aneurysmally dilated aorta is the result. Hence a high pulse pressure, which many look upon as evidence of an efficient circulation, is injurious. I have often said that when the pulse pressure exceeds 40 mm. of mercury it is time to be thinking about repairs.—I am, etc.,

Liverpool, Feb. 19th.

JAMES BARR.

SIR,—I very much regret that a slip led to errors in writing the integration on p. 261 (col. 2) of the above article. Lines 14-17 should read:

$$\text{For the sphere } p = \frac{2t}{\sqrt{\frac{3}{4\pi}}} \\ \therefore W = \int \frac{\sqrt{3}}{\sqrt{4\pi}} \frac{2t}{\sqrt{\frac{3}{4\pi}}} V^{-\frac{1}{2}} dV \\ = 3t \sqrt{\frac{4}{3\pi}} (\sqrt{V_2^3} - \sqrt{V_1^3})$$

t being constant in this type of membrane.

Line 46 should read:

$$\left(\frac{dp}{dn} \propto \frac{R_0}{(d_0 + n)^2}\right)$$

—I am, etc.,

Birmingham, Feb. 21st.

CRANSTON WALKER.

THE TREATMENT OF EMPYEMA.

SIR,—I should like to endorse what Mr. Philip Turner says (p. 329) about the use of Bier's cups in empyemata. I have used them for some years, not as a matter of routine but whenever the drainage seemed to be unsatisfactory. Everyone is familiar with cases in which all goes well up to a certain point, and then improvement seems to stop. There is often a sinus with a small pocket at the end in which pus accumulates and discharges periodically. In these cases Bier's cup, if it can be properly applied, is invaluable; it ensures the emptying of the pocket and promotes healing. Unless the sinus is very deep a smaller cup than the three inch is quite effective, and generally much more easily applied to the chest.

The rapid and complete healing up of these sinuses is not a trivial matter, as their persistence seems often to be the determining cause of the occurrence of cerebral abscess, the most formidable and not infrequent sequel of empyema. Out of six cases due to intrathoracic trouble which I have seen in the last few years three were connected with persistent fistula.—I am, etc.,

Brighton, Feb. 25th.

E. HOBHOUSE.

SUICIDE IN BORDERLAND CASES.

SIR,—Dr. S. E. White (BRITISH MEDICAL JOURNAL, February 18th, 1922) says the aim is to "prevent the suicidal tendency." Everybody will agree, but short of the regulation of everybody's mental processes it is difficult to see how this ideal can be realized. Many cases do not come under medical advice until the suicidal tendency has actually come into existence—and then, unfortunately, in some a waiting policy is adopted or the danger is not realized.

Surely it would be better to direct our energies to educating the public to understand that sufferers from mental disorder should be regarded in the same light as those with bodily diseases, so that treatment will be sought as early as possible, instead of perpetuating the idea that insanity is a disgrace to which a "taint" attaches. There is no difference, in principle, between the isolation of patients with mental disorder and those with other diseases which require special measures in their own interest or in that of the public.

Dr. White makes sweeping charges against the Lunacy Board and asylum authorities. Dr. Edwin Gondall's letter, which immediately precedes it, is highly appropriate. To refer to one or two details, I know personally of cases in which apparently inadequate certificates, or those with technical errors, have been unaccepted until amplified or corrected; to "invalidate" them without inquiry, thus involving the patient's release, would entail grave risks. I also know of a case—not in England—where the authorities corresponding to the English Lunacy Board, on the application of a patient in a mental hospital, gave him so much liberty under conditions defined by them, in spite of the protests of the medical officer, that he was enabled to commit suicide promptly.

Has Dr. White never heard of voluntary boarders and ex-certified patients applying for readmission when they feel the approach of a relapse? What does Dr. White want? She practically alleges that the Lunacy Board fails to protect the helpless, and wrongfully allows detention in asylums, but would have homes for uncertified (not necessarily uncertifiable) cases kept free from any link with the Board. Who is to see that cases which require certification are not so detained, and that the homes do not become an even more serious "menace to liberty" than the Scottish system she dislikes? It is evident that in Dr. White's opinion the various local authorities and justices are useless as a protection, and are all parties to abuse of the Lunacy Law—to say nothing of the asylum staffs.—I am, etc.,

E. C. PLUMMER.

Neurological Clinic, Plymouth, Feb. 19th.

HENRY OF NAVARRE.

SIR,—You kindly published a long and admirable abstract of my Thomas Vicary lecture on December 17th. I did not know you intended to publish this abstract, and I had no opportunity of correcting it. There was one mistake (p. 1041). Henry of Navarre was substituted for Philip of Nassau. Presumably Dr. Clowes has been led astray by this mistake; he could not have been present at my lecture, neither can he have had an opportunity of reading it *in extenso* (Lancet, January 28th, p. 167). The following is taken from the lecture. Guthrie was an opponent of the mediæval practice of frequent and multiple trephining, and he gives the following case (and others) in support of his views:

"Philip of Nassau having been thrown from his horse fractured his skull in several places by striking his head against the stamp of a tree. He was trepanned 27 times by a surgeon of Neomagen. He gave a certificate of this, signed by himself, and Solingen adds as a proof of his complete recovery that he drank 3 of his companions to death." (Guthrie, *Injuries of the Head Affecting the Brain*, 1847, p. 153.)

Guthrie quotes the story from Solingen (*Manuales Operationes Chirurgie*, cap. vii, p. 29). Solingen's work is not in the library of the Royal College of Surgeons and is not in the library of the Royal Society of Medicine. It was in the library of the Medical Society of London, but has apparently been lost.

I should be much obliged if Dr. Clowes would tell me who Philip of Nassau was and all about him.—I am, etc.,

London, W., Feb. 26th.

C. A. BALLANCE.

THE NAVAL MEDICAL SERVICE.

SIR,—It seems very probable that the medical services of the Navy, Army, and Air Force will all be merged into one, and this great change, apart from any question of economy, will indeed be a fortunate thing for the Naval Medical Service, which otherwise would seem destined to perish from inanition due to the lack of suitable candidates, as well as to neglect by those in authority to represent the best interests of that service to which they belong. The silent but nevertheless seething criticism passed by those temporary medical officers who served during the late war (I believe that out of about 860 temporary surgeon lieutenants only some 2 or 3 per cent. elected to become permanent on the offer being made by the Admiralty) must be apparent even to the dullest intellect. One reason given for this by a very keen and able young medical officer was that he would not wish to remain in a service where senior medical officers were treated with such scant consideration.

The placing on the retired list of senior men, who had reason to suppose that the Admiralty would honour its obligations, and that they would reap a small return for their long and often arduous service during and also after the war; the very slight increase to the ordinary pre-war pension, as compared with other branches of the service; the casual and curt way in which these senior officers are placed on the retired list, without, in some cases, even any decent warning—these, and many other considerations, have created a feeling of much bitterness and resentment. This feeling is naturally known to the junior officers, and it would not be surprising to hear that they were keen to get out of the service at the first favourable opportunity.

All these facts cannot but fail to react on the Naval Medical Service itself, where good, but often unrecognized, work is being done.—I am, etc.,

February 8th.

"EXPERTO CREDE."

CLAYDEN v. WOOD-HILL.

SIR,—I am sending you the sixth list of subscriptions to the Wood-Hill Fund, which I shall be obliged if you will kindly insert in your next issue.

In the original letter, published in the JOURNAL on December 3rd, 1921, appealing for contributions in aid of Dr. Wood-Hill, it was stated that the total expenses incurred by him, including the damages awarded, would be about £1,600. I have recently heard from the solicitor for the defence, and I regret to say that the original provisional estimate of £1,600, made immediately after the trial, will be considerably exceeded, owing mainly to the large claim for costs sent in on behalf of the plaintiff. Dr. Wood-Hill's total liability will be not less than £2,250.—I am, etc.,

HAMILTON A. BALLANCE,
Honorary Treasurer.

All Saints Green, Norwich,
February 25th.

Sixth List of Subscriptions.

Amount previously acknowledged, £938 8s. 6d.

£20 14s. 4d. Fife Branch of the B.M.A., per Dr. D. Elliot Dickson, Hon. Sec.	L. Rollason, H. D. Rollinson, and H. P. Thomason

	Mr. L. P. Costobadie, Mottram

Obituary.

CHARLES DRAGE, M.D.,
Late of Hatfield.

DR. CHARLES DRAGE, formerly of Hatfield, died recently at his daughter's residence in Herefordshire at the age of 97. He was a student at St. Bartholomew's Hospital, took the diplomas of M.R.C.S. Eng. and L.S.A. in 1848, and graduated M.D. at King's College, Aberdeen, in 1857. After a short apprenticeship at Ipswich he settled in practice at Hatfield where he practised continuously for some sixty-five years until his retirement in 1912. He was one of the best known men in south Hertfordshire, which when he settled in Hatfield was still a purely agricultural district containing the seats of many distinguished persons. Dr. Drage belonged to the best type of general practitioner, and kept himself well acquainted with the progress of medicine and surgery, with perhaps a special leaning to the latter. At one time he was a frequent visitor to the operation theatres of London hospitals. Dr. Drage was a tall, well-proportioned man of striking appearance, and was endowed with remarkable energy and a robust constitution, a combination which enabled him to get through an immense amount of work. One of his earliest patients was the great Duke of Wellington, and he was medical attendant to three Prime Ministers—Lord Melbourne, Lord Palmerston, and the late Lord Salisbury. With the changes in south Hertfordshire, which converted it into a kind of residential outskirts of London, Dr. Drage got into the habit of spending much time in London, running up to see patients who had come under his care in Hertfordshire. Dr. Drage was for many years a member of the British Medical Association, and served on the Council, but he did not approve of the changes made in 1883, and his active interest in the Association thereafter greatly diminished.

He retired in 1912 and went to live with his daughter at Rodd Court, Herefordshire. He had three sons: one of them, Dr. Lovell Drage, who died in 1919, was associated in practice with his father, and was also coroner for Hertfordshire; another is a clergyman in Yorkshire; and the third, Mr. Geoffrey Drage, is the well known writer on economics and politics, who was formerly M.P. for Derby.

DR. JOSEPH BRINDLEY-JAMES, who died on February 20th, was born in 1849 at Aberystwith, the son of Dr. Thomas James. He was educated at Shrewsbury Grammar School and subsequently at King's College, London. He took the diplomas of M.R.C.S. Eng. in 1876, and L.R.C.P.I. in 1894. He was president of the Association of Members of the Royal College of Surgeons, and a vice-president of the Medical Sickness Annuity and Life Assurance Society, of which he was one of the original members. He was an Associate of King's College and honorary physician to St. Mary's College, Brook Green. Up to the end of last year Dr. James had been a member of the British Medical Association; he had also served as a member of the Barnes District Council. A memorial service was held at Holy Trinity Church, Barnes, on February 25th, and the interment took place at East Sliden.

We are indebted to Dr. Herbert E. Friend (London) for the following: It will interest your readers to hear that there passed away on February 16th what must surely have been the last of the old army surgeons who saw service in the Crimean war—at the age of 96. The Rev. JAMES GEORGE was the son of Dr. George, who practised in Kensington at the end of the eighteenth and beginning of the nineteenth centuries. He was born in 1826, and in due time became a pupil at St. George's Hospital under Caesar Hawkins and Tatum on the surgical side and Benice Jones and Nairn on the medical. Taking the M.R.C.S., he joined his father in his practice, but later—in 1853—received a surgeon's commission in the army, and was present in the Crimea during the war: he later contracted small-pox, on his recovery from which he decided to give up medical work and to take Holy Orders. Until comparatively recently he lived in the country, leading the quiet life of a country vicar, retaining his faculties to the last.

DR. HOWARD B. CROSS of the Rockefeller Institute of Medical Research, who went to Mexico in December last to study yellow fever, contracted the disease in the centre of the yellow fever district, and died on December 27th, at the age of 32.

Universities and Colleges.

UNIVERSITY OF OXFORD.

At a congregation held on Saturday, February 18th, the following degree was conferred:

D.M.—E. W. M. H. Phillips, Jesus College.

UNIVERSITY OF LONDON.

At a meeting of the Senate on February 22nd, Professor H. R. Dean, M.A., M.D., B.Ch.Oxford, F.R.C.P., was appointed as from June 1st next to the University Chair of Bacteriology, tenable at University College Hospital Medical School. He held the Salters' Company's Research Scholarship in Pharmacology in 1906 and the Radcliffe Travelling Fellowship of the University of Oxford from 1909 to 1911, when he studied in Berlin. After holding various appointments at St. Thomas's Hospital and the Lister Institute, he became Professor of Pathology in the University of Sheffield. Since 1915 he has been Professor of Pathology and Pathological Anatomy in the University of Manchester.

UNIVERSITY OF LEEDS.

William Hey Medal in Medicine and Surgery.

PROFESSOR SIR BERKELEY MOYNHAN, K.C.M.G., C.B., F.R.C.S., has given to the University of Leeds an endowment for the annual award at the Leeds Medical School of a gold medal to the best student of the year in medicine and surgery. The gold medal will bear the name of William Hey in commemoration of the work of that great Leeds surgeon. The Council of the University in accepting the endowment have recorded their thanks to Sir Berkeley Moynihan for his generous gift.

William Hey (1736-1819) was one of the pioneers of modern surgery. A brilliant operator and teacher, he established the tradition of surgical skill which has ever since been one of the chief distinctions of Leeds. He was a friend of Joseph Priestley when the latter was minister of Mill Hill. He took an active part in the foundation of the Leeds Infirmary, of which he was senior surgeon from 1773 to 1812. His statue by Chantrey stands in the entrance hall of the infirmary. His son William (1772-1844) and his grandson, the third William Hey (1796-1875), were also eminent surgeons, the latter being one of the founders of the Leeds School of Medicine in 1831. The medical traditions of the family were carried into the fourth generation by two great-grandsons of the first William Hey—namely, Samuel Hey and Edward Atkinson—who respectively served the Leeds Infirmary as surgeons from 1850 to 1872 and from 1874 to 1894.

Medical News.

THE Royal Society of Medicine has adopted a new by-law permitting the election as associates of medical men and women, whether British or otherwise, within five years of their first professional qualification. An Associate will be entitled to the privileges of Fellows other than that of voting or holding office, but will only be allowed to borrow one volume at a time; he will pay an annual subscription of three guineas, but no admission fee, and if after having paid three annual subscriptions he is then elected a Fellow, will not be required to pay an admission fee.

THE fifteen candidates selected by the Council of the Royal Society to be recommended for election into the society include Dr. C. G. Douglas, C.M.G., M.C., of St. John's College, Oxford, and Dr. M. S. Pembrey, lecturer on physiology at Guy's Hospital and professor and examiner in physiology in the University of London.

DR. F. GOWLAND HOPKINS, F.R.S., Professor of Biochemistry in the University of Cambridge, and Dr. William Halse Rivers, F.R.S., President of the Royal Anthropological Institute, have been elected members of the Athenaeum Club under the rule which empowers the annual election by the committee of a certain number of persons of distinguished eminence in science, literature, the arts, or for public service.

THE fourth Italian Congress of Medical Radiology will take place at Bologna, in the Rizzoli Orthopaedic Institute, from May 9th to 11th, with Professor Aristide Busi as president. In connexion with the congress an exhibition of radiological apparatus will be held. Further information may be had from the secretary of the congress, Dr. Alberto Possati, Villa Verde, Bologna.

A THREE months' course of lectures and demonstrations in hospital administration will be given at the North-Western Hospital for Infectious Diseases, Lawn Road, Hampstead, by the medical superintendent, Dr. E. W. Goodall, on Mondays and Thursdays, at 5.15 p.m., beginning on April 3rd. The fee for the course is £33s., which should be paid to the Clerk to the Metropolitan Asylums Board.—A course of instruction in the diagnosis and treatment of fevers will be

during the month of May. A two months' course will be held in August and September, and a further course will commence in October. Full particulars can be obtained on application to the Clerk of the Metropolitan Asylums Board, Embankment, E.C.4.

WE regret to announce the death, at the advanced age of 95, of Dr. Alfred Hill, for many years medical officer of health for Birmingham, and for nearly seventy years a member of the British Medical Association. We hope to publish a memoir in an early issue.

THE King's Services Choirs consist of ex-service men from the various hospitals where neurasthenics, mainly sufferers from shell shock, are treated. They are trained and maintained by the Vocal Therapy Society, and on February 11th they gave a demonstration of the value of the treatment which they receive. The men demonstrated their capacity for singing in harmony as well as in unison as separate choirs and as a combined mass, and the effect upon the men as well as on the audience of interested supporters was most inspiring. The beneficial effect of the activities of this society make it worthy of generous support; reports can be obtained from the secretary at 27, Grosvenor Place, S.W.1.

DR. EDITH M. BROWN, of the Zenana Bible and Medical Mission, and for twenty-eight years principal of the Women's Christian Medical College, Ludhiana, Punjab, India, has had the honour of Fellowship of the Punjab University conferred upon her in recognition of her work.

At a meeting of the British Spa Federation recently held in London it was resolved that the tariff in operation at the British spas be reduced for the coming season, and that the hotels, hydros, and places of accommodation be recommended also to reduce their tariffs considerably. Railway facilities to the spas was also recognized as a matter of importance, and the Federation intends to press for at least a revival of the twenty-eight day facilities granted before the war. The honorary secretary of the Federation is Mr. F. J. C. Broome, general manager of Harrogate Spa.

AN action for damages against Inecto Limited and a hairdresser was heard before Mr. Justice Bailhache in the King's Bench Division on February 24th and 27th. The plaintiff, who was a music-hall artist, said that she went to the hairdresser's shop to have her hair dyed black for the purposes of a part she was playing. Shortly after the application she felt an irritation in her head; this afterwards became so much worse that she was under treatment at Charing Cross Hospital from March 12th till April 5th. Medical evidence was called to support the plaintiff's case. One of the witnesses was Dr. J. M. H. MacLeod, who said that the substances stated to be in the compound—paraphenylenediamine and resorcin—were both irritants of the skin. No evidence was called on behalf of the company. The hairdresser stated that he had had ten years' experience of using Inecto Rapid and only once before had he had a complaint about it. The action against the hairdresser was dismissed but without costs. In giving judgement, Mr. Justice Bailhache said that the warning sent out by Inecto Limited at the time was not sufficient to protect them in such a case, but that that now issued was much more complete and seemed to him sufficient. He found the company liable in damages, which he assessed at £200, and gave judgement for that amount with costs.

THE King of the Serbs, Croats, and Slovenes has conferred the Order of Saint Sava upon Dr. Mary Alice Blair (Class IV) and Dr. G. K. Bowes (Class V), the former in recognition of services rendered in connexion with the Serbian Relief Fund, and the latter for valuable services rendered during the war.

FESTIVITIES are being arranged to take place early this year in celebration of the foundation of the University of Padua in 1222. Professor Lucatello, the Rector of the University, is arranging the ceremonies.

THE Chairman of the London Hospital, Viscount Knutsford, announced at a meeting of the Governors on March 1st that the Committee, on the advice of the Medical School staff, has decided that no more women students will be trained at the hospital.

THE second general assembly of the thirty-seven national societies which are members of the League of Red Cross Societies will meet in Geneva on March 25th to 31st. The British Red Cross Society will be represented by Sir Arthur Stanley, G.B.E., Sir Napier Barnett, K.B.E., M.D., and Sir George Newman, K.C.B., M.D. The report of the Secretariat will be presented by Sir Claude Hill, K.C.S.I., Director-General of the League. The assembly will then discuss a programme of popular health education.

THE number of deaths from influenza in the week ending February 25th showed a further decrease. In the 105 great towns the figures were 525 against 670 in the preceding week.

THE annual meeting of the Central Council for District Nursing in London took place on February 23rd, at the offices of the Metropolitan Asylums Board. The question of extending the area of the work of the Central Council to include the whole of the metropolitan police area was considered, but no definite action has yet been taken; it was felt that it would be best if a voluntary district nursing association could be established in each district. It was agreed that there was a demand for adequately trained home helps, who, however, should not be allowed to drift into being amateur nurses, and that their training could best be supplied by the infant welfare centres. Inquiries had been addressed to all the federated district nursing associations in regard to the nursing of septic cases and practically all had now declared their willingness to undertake the nursing of such cases under the direction of a doctor. During the year grants were distributed to the district nursing associations of the metropolis amounting to £7,415, and besides the £4,000 remaining of the grant made by the British Red Cross Society there was a balance in hand of £2,000, which the Executive Committee proposed to allocate to special needs and to opening up new districts.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Atiology*, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Mediscera*, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus*, Dublin; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate*, Edinburgh; telephone, 4361, Central).

QUERIES AND ANSWERS.

"E." invites any member, who has had personal professional experience, to say whether excision of one or both testicles in a middle-aged married neurasthenic, whose symptoms seem primarily to arise from a neuralgia in these glands, is likely to be effective as a cure.

INCOME TAX.

"LAPIS" holds a County Council appointment, and inquires (1) whether he is entitled to deduct the expenses of subscribing to this and other medical journals; and (2) whether he is entitled to the benefit of the three years' average.

*(1) In our opinion, Yes. We consider that a reasonable expenditure on current medical literature of a general character can properly be said to be incurred wholly, exclusively, and necessarily in the performance of the duties of the office. In our experience, however, we find that local inspectors of taxes are inclined to take the contrary view where the more stringent rule under Schedule E applies (as it does here), though allowing the expenditure where the general rules of Schedule D apply, as they do in the case of a private practice. The point does not appear to have been carried to the High Court, but "Lapis" might succeed in an appeal to the local Commissioners of Taxes. (2) No. This is unfortunately beyond dispute. The emoluments of a public office are assessable under Schedule E on the basis of the actual emoluments of the year, and that rule is, so far as we know, applied without qualification or concession.

"T. N. G." bought a car for £350 in 1909, and another for £260 in 1917, retaining the original car until 1918, when it was sold for £59. He asks what allowance he can claim.

() The second car was bought to replace the first, and the fact that both were retained in hand for some time does not alter the fact that the circumstances as a whole justify a claim to treat the second car as a replacement. The loss on the first car was £350-£59=£291, but we understand that the Revenue authorities claim that the maximum allowance is the actual out-of-pocket expenditure incurred on the replacement, which

would be £260-£59=£201. "T. N. G." appears, therefore, to be entitled to an allowance of at least that amount as for either 1917 or 1918, and seeing that the amount was indeterminable until 1918 that would seem to be the appropriate year for the allowance.

"BRUNSWICK" inquires why a salary for contract work at a large works should be taxed separately when panel receipts are pooled with the general private practice receipts.

() Assuming the salary to be paid by a joint stock company it is legally separately assessable under Schedule E; we may, however, say that some time ago the Board of Inland Revenue agreed to treat hospital part-time salaries as part of the general practice receipts, and there seems to be no reason why they should not deal similarly with a contract salary paid by a company.

LETTERS, NOTES, ETC.

A CONFUSION OF NAMES.

MR. J. T. AINSIE WALKER (London, E.C.), in the course of a communication, refers to the letter (p. 331) by Dr. E. W. Ainley Walker of Oxford disclaiming connexion with any antiseptic of commerce. Mr. Ainsie Walker states that the introduction of the benzene derivative dimol to the scientific world was made in accordance with strict ethical canons in a paper read at the International Congress at Brussels in 1920, and that the Anglo-French Drug Company are responsible for the commercial introduction of dimol to the medical profession. He adds: "If Dr. Ainley Walker's letter has the effect of directing my correspondence into the proper channels we shall both be spared any further annoyance and inconvenience."

ALPINE TREATMENT OF TUBERCULOSIS.

DR. FELIX SAVY (Grampian Sanatorium, Kingessie, Inverness-shire), in the course of a letter, writes: I cannot agree with your correspondent Sir Martin Conway that "the passport tyrants in all Foreign Offices and Consulates, and other interferences with free international travel resulting from the war, have had a disastrous effect upon the treatment of tuberculosis." It seems difficult to say on what grounds and for what purpose he makes this sweeping and not too generous statement. The Alpine resorts for the treatment of pulmonary tuberculosis are very much overrated, and also very much advertised. Egypt, the Canary Islands, and South Africa have had their day. Now it is Switzerland. The medical profession have had an opportunity of testing the result of treatment in our "damp and sunless" climate during the last twenty-five years or more, and I venture to say that a good many of us are satisfied that results as satisfactory can be obtained in British sanatoriums. If Sir Martin Conway will compare the results of treatment in some of our leading sanatoriums with similar institutions in Switzerland he could satisfy himself on this point. We hear about the wonderful cures from Switzerland. We hear little or nothing about the failures. The Swiss climate is certainly ideal for the sun cure in surgical tuberculosis; but it is not always the ideal climate for pulmonary tuberculosis. Before the war the Queen Alexandra Sanatorium and other institutions in Switzerland found it difficult to carry on, chiefly because few patients cared to spend the summer months there, when the climate is, if anything, worse than ours. These institutions were running at a loss because these patients did not find it disastrous to spend the summer months in British sanatoriums. The class of patient for which Sir Martin Conway is appealing would, I venture to say, do just as well under treatment in a sanatorium in this country. They do not belong to the idle rich class, who can afford to go to Switzerland winter after winter. Most of them have to earn their living; for them to undergo the cure in the same climate in which they are going to live and work is preferable. I believe this is the view held by many experts in this and other countries.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 32, 33, 36, and 37 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 34 and 35.

THE following appointments of certifying factory surgeons are vacant: Acle (Norfolk), Newton Abbot (Devon), St. Boswells (Roxburgh).

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	0 9 0
Each additional line	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 15 0
Half page	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive postal remittance letters addressed either in initials or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

202. Skin Tests with Foreign Proteins.

RACKEMANN (*Amer. Journ. of Med. Sci.*, vol. 163, January, 1922) reports on skin tests with fifteen different proteins in a long series of patients in whom sensitiveness to protein was a reasonable and probable explanation of their condition. The method employed was either the cutaneous, in which the dried protein is scratched into the skin, or the intradermal, in which a measured quantity of sterile protein solution is injected between the layers of the skin. Since the latter method has been found by Walker to be less specific and too sensitive, the cutaneous reaction was the one chiefly used by Rackemann. In hay fever and pollen asthma about 40 per cent. of the patients showed positive tests to some protein other than pollen. Those who gave positive tests to cereals were all unaware of the sensitiveness before the test was made, and withdrawal of the particular protein from the diet made no difference to the symptoms. From the unexpected reactions obtained to proteins in patients suffering from horse asthma and dust asthma the author concludes that the finding of a positive test does not explain the cause of the symptoms, and it is only when the sensitiveness is confirmed by the patient's history or subsequent behaviour that any importance should be attached to a positive result. The findings were of no practical value in emphysema, and no benefit followed protein treatment. In other diseases tested, including rhinitis, eczema, urticaria, and angio-neurotic oedema, and a large number of other conditions, the food protein test gave no very reliable information. As to the value of skin tests in general, the opinion is expressed that in hay fever, horse asthma, and dust asthma, when the history shows a fairly definite and obvious relation of symptoms to some one protein, the skin test demonstrates this protein etiology, and is useful in treatment to determine the dilution of pollen extract to use at the start. In the present series, amongst diseases other than hay fever, 100 cases showed positive results to some form of protein, but in only 13 of these cases was the finding of the test to food or animal protein really important and of use in further treatment. Still, in these cases it was useful, and it is questionable whether the idiosyncrasy would have been diagnosed by any other method.

203. The Fatal Dose of Arsenic.

JOACHIMOGLU (*Klin. Woch.*, January 21st, 1922) points out the difficulty in determining the fatal dose of arsenic in man, since in poisoning cases the exact quantity taken is so often not known, and frequently a considerable amount of the poison is vomited. He tabulates seven cases from medical literature in which the quantity of arsenic taken was known. In one case 0.4 gram of arsenious acid was taken without bad effects, but the man was an arsenic eater. In the other six cases tabulated large quantities of arsenic were taken and yet recovery followed, but vomiting had occurred. Joachimoglu records, however, a case in which a teaspoonful of arsenious acid (= about 12 grams) was taken along with morphine, and though no vomiting occurred the dose was not fatal. The stomach was not washed out for twenty-four hours. Arsenical neuritis followed, but by the end of nine months the neuritis had almost disappeared. The case was evidently one of idiosyncrasy, since the fatal dose for an adult is usually 0.1 to 0.2 gram (1/3 to 3 grains); and 0.06 gram has caused death. The author obtained a definite arsenic reaction on examining 5 grams of the hair of the case recorded, five months after the poisoning.

204. Cinchonine and Malaria.

SANGUINETTI (*Il Politecnico, Sez. Prat.*, December 5th, 1921) has treated ten cases of benign tertian malaria with cinchonine hydrochloride, given in tablets of 20 cg. each, the doses used being identical with those used in the treatment of malaria with quinine salts. In all the patients so treated the febrile attacks ceased at once and did not recur during the period of observation. Sanguinetti does not maintain that cinchonine can be substituted for quinine in every case, but is of opinion that it can be used freely, not only in cases which show resistance to or intolerance for quinine, but also, in the ordinary management of benign tertian and quartan fevers. Sanguinetti is of opinion that considerable benefit will be derived from the use of cinchonine, in view of the difficulty in obtaining a sufficient quantity of quinine for all the cases of malaria in Italy.

205. Results of the Modern Treatment of Syphilis.

VAN DEN HEUVEL (*Nederl. Tijdschr. v. Geneesk.*, December 17th, 1921) states that 577 cases have been treated in the venereal department of the Naval Hospital at Willemsoord, Holland, by the following methods: (1) Mercury only, 184 cases; (2) mercury followed by neo-salvarsan, 190 cases; (3) combined treatment, 203 cases. In the first group the Wassermann reaction became negative in 95, or 52.1 per cent.; in the second group in 114, or 60 per cent.; and in the third group in 129, or 63.5 per cent. Tertiary and parasymphilitic symptoms developed in spite of treatment in 7 cases, or about 4 per cent., of the first group; in 10 cases, or about 5 per cent., of the second group; and in 1, or about 0.5 per cent., of the third group. In the third group also 2 cases developed iritis, 2 chorio-retinitis, and 1 retinitis during treatment. Van den Heuvel's conclusions are as follows: (1) Although the modern treatment by neo-salvarsan and mercury combined yields better results, especially as regards rapidity of cure, than treatment by mercury alone, they are still far from satisfactory. (2) Examination of the cerebro-spinal fluid should be made (a) after a cure intended to abort the disease, (b) after incomplete treatment, (c) in cases in which the Wassermann reaction remains strongly positive in spite of long-continued treatment. (3) The time is not yet come, nor is the treatment of syphilis sufficiently uniform, to enable one to decide whether parasymphilitis is more frequent as the result of modern treatment.

206. Vascular Syphilis.

ÉTIENNE (*Arch. des mal. du coeur*, October, 1921), in a report made to the fourteenth French Medical Congress at Brussels in May, 1920, states that aortitis is extremely frequent in syphilis. Simple aortitis without lesions of the sigmoid valves or aneurysmal dilatation forms about 40 per cent. of all the aortic localizations of syphilis. Aneurysm was found in 30 per cent. of Étienne's cases, an unusually high proportion. As regards the clinical symptoms of syphilitic aortitis, sometimes the condition is entirely latent, while in others serious symptoms arise with alarming suddenness. Pain assumes a different character according to the patient. In one of Étienne's cases it was situated in the epigastric region and recurred in violent gastric crises, as in tabes. The autopsy, however, showed that it was due to a supra-sigmoid aortitis with stenosis of the coronary arteries. As regards treatment, Étienne prefers mercury to arsenobenzol, which may expose the patient to the risks of oedema of the lung. There is the same danger with potassium iodide when renal insufficiency is present.

207. Treatment of Erysipelas in the Newborn.

BOISSERIE-LACROIX (*Journ. de Méd. de Bordeaux*, January 25th, 1922) gives an account of three cases of erysipelas in the newborn and young children treated with local applications of antistreptococcal serum. Two of the cases were marked by serious relapses, which appeared a few days after treatment had been stopped. They quickly recovered, however, with fresh applications of serum. The serum is applied over the area affected, and repeated three times a day till the condition, both locally and generally, resolves, which usually occurs within a week. In one case subcutaneous injections of antistreptococcal serum were also given. All the cases were cured, and considering the gravity of this affection in young children, the results are distinctly encouraging. This form of treatment is absolutely devoid of risk, and there is no fear of anaphylaxis or other serious accidents. The author advises that this method should be systematically employed in treating erysipelas in children, and the applications should be continued for a time after the rash has disappeared, to avoid the danger of a relapse.

208. The Length of the Intestine and the Sitting Height.

JELLINEGG (*Wien. Klin. Woch.*, December 15th, 1921) states that von Pirquet chose the sitting height as a standard for determining the daily nutritional requirements of the human organism, and that he estimated that the length of the intestine was ten times that of the sitting height, starting with the idea that the amount of nourishment required must depend on the size of the absorbent intestinal surface. In 36 cases in which careful measurements were made by Jellinegg on children aged from ten days to twelve years, the average relation between the sitting height and the length of the intestine was found to be 1 in 11.9, the lowest calculation being 1 in 8.2, and the highest 1 in 15.8. These measurements

thus show extraordinarily great individual variations in the relation between the sitting height and the length of the intestine. Jellineg therefore concludes that it is unjustifiable to generalize as to the relations between the sitting height and the length of the intestine, or to estimate the size of the absorbent intestinal surface on the basis of these relations.

209. Pneumococcal Infection in Infants.

RENARD (*Journ. de méd. et de chir. prat.*, November 23rd, 1921) in his Paris thesis states that epidemics of pneumococcal infection are observed in crèches at certain seasons of the year. The infection usually begins in the nasopharynx, which is the principal factor in the contagion. Pneumococcal rhino-pharyngitis is characterized by its persistence, contagiousness, and frequency of pulmonary complications. It appears in three forms—namely, a mild form without fever, an acute form with high fever, profuse purulent nasal discharge giving rise to attacks of suffocation, and a subacute protracted form. The infection may often be complicated by otitis, in the pus from which the pneumococcus is frequently found. The prognosis of this form of otitis is good. Pneumococcal bronchopneumonia is frequent, and is characterized by sudden onset, high fever, and intense dyspnoea. The prognosis is grave. The bronchopneumonia is often complicated by purulent pleurisy, with which suppurative pericarditis is sometimes associated. The latter complication, which is usually not diagnosed during life, is always fatal. Involvement of the meninges may occur during the course of bronchopneumonia, or the pneumococcus may give rise independently to meningitis, which may be serous or suppurative. Arthritis and peritonitis are less frequent localizations of the pneumococcus. Pneumococcal infection may also run its course without visceral lesions in the form of septicaemia, sometimes accompanied by purpura.

210. Hilum Tuberculosis.

CANTANI (*Studium*, January 20th, 1922) draws attention to a sign which is often to be detected in hilum tuberculosis, although there may be few if any clinical symptoms. It consists in the presence of pleural crepitus heard along the parasternal and right paravertebral line and at the cardio-hepatic angle. The sign may be elicited by cough, and is not always constant. Nor is it pathognomonic of hilum tuberculosis, but coupled with slight dullness in the same area it should arouse strong suspicion. The author has corroborated his observations by radiographic examination. The sound in question is pleural, and probably due to a direct spread along the pleura from the root and ligament of the lung. He points out that hilum disease may exist without giving rise to any symptoms, but as it may be an initial phase of pulmonary tuberculosis, any observation which renders the diagnosis of the condition more easy is worth recording.

SURGERY.

211. Treatment of Gastric and Duodenal Ulcer.

DE QUERVAIN (*Surg., Gynec., and Obstet.*, January, 1922) discusses the relative merits of resection and gastro-enterostomy in the treatment of gastric and duodenal ulcers. He bases his report on a study of the end-results of 247 cases. Operation is advised when stenosis or repeated bleeding is present and endangers the patient's life or when persistent symptoms resist all efforts at medical treatment. With regard to diagnosis, he considers too much importance is attached to the part played by hydrochloric acid. The percentage of cases showing hyperacidity is far less than the percentage showing normal or subnormal acidity. Lactic acid was not detected in any case found benign at operation. Occult blood in the stools is usually found in carcinoma cases, in 50 per cent. of gastric ulcers, and in 65 per cent. of the duodenal ulcers. X-ray examination gave definite localization of gastric ulcer in 87 per cent. of cases. In duodenal ulcer exact localization was possible in 54 per cent. of cases. Carcinomatous degeneration of a benign ulcer was demonstrated in 1.4 per cent. of the cases. The operative mortality after gastro-enterostomy was 6.5 per cent., after radical operation 7.7 per cent. The most important causes of death were emboli, pneumonia, and lung gangrene. Jejunal ulcers were found eight times in his cases, twelve times after operations done elsewhere. He uses fine catgut for suturing, reinforcing with cotton stitches. Because of the danger of peptic ulcer and bleeding from the primary ulcer he leans towards resection. With regard to late results, observations made in the first four years after operation do not contain all the possible sequelae. Simple gastro-enterostomy produces in all forms of gastric ulcer the same early results—about four-fifths. Over longer periods cure or

improvement is found in 75 per cent. of cases. Radical methods for all periods show a cure in 80 per cent. of cases. As to the method of operation, V-shaped excision is unsatisfactory. The so-called sleeve operation gives good results. The end-to-side anastomosis of stomach and jejunum has yet to be reported. He concludes that, if properly executed, resection yields better end-results than whether in a case of gastric or duodenal. There is a satisfactory reason for employing resection even though it involves greater operative risk. If external conditions are not satisfactory, one can, with good conscience, decide not to resect. It is better to do a good gastro-enterostomy than resect under unfavourable circumstances.

212. Syphilis of the Bladder.

COSACESCO (*Journ. d'Urologie*, November, 1921) points out that syphilis of the bladder appears to be a rare condition and seldom diagnosed, judging by the number of published cases. But this affection, whilst not common, is more frequent than is supposed, and many cases pass unrecognized. The fact that it is not more often found is probably due to the absence of irritation, so common in the mouth and anal region, and to the circumstance that being hidden from direct view it is able to pass unrecognized. Cosacesco has recently had a case of this nature under his care, which had been diagnosed as tuberculous or gonococcal cystitis for a period of eight years. Most observers have laid stress upon the cystoscopic appearances of the bladder, but this is not a certain means of diagnosis. A chancre in this situation has not yet been described. In the secondary stage an eruption appears similar to that of the skin and mucous membranes—ulcers of different types round the ureteric orifices, trigone, and base. In the tertiary stage gummata and ulcers may be found. Syphilis of the bladder may be undistinguishable from an innocent or malignant growth, and the bladder has even been opened under a mistaken diagnosis. The cystoscopic appearances are therefore very varied, and they must be supplemented by other methods of diagnosis. From a clinical point of view, frequent micturition is usually though not always present. Pain may be present, and is noticed on palpation over the bladder. There is usually haematuria, which may be slight or very profuse. Retention is rarely noticed. The urine may be acid or alkaline, containing epithelium and cells, and frequently bacteria. There are two clinical types which can be recognized: (1) Accompanied by a superadded cystitis, the commonest variety; characterized by its long duration without affecting the patient's general condition, and lack of response to usual forms of treatment. (2) The type with haematuria as its only symptom. The cystoscope, when it shows the characteristic lesions present, is an excellent means of diagnosis, but one must not overlook the fact that malignant growths and ulcers may give the same appearance. The Wassermann reaction and the effect of antisyphilitic treatment should be tried in all bladder affections where the condition is not evident, and these are im-
pro-

213. Treatment of Anthrax.

MONTELEONE (*Il Policlinico, Sez. Prat.*, November 28th, 1921), in the course of four months at the Policlinico Umberto I at Rome, has observed 36 cases of malignant pustule (anthrax), in 33 of which there was a single pustule; in 1 two pustules, and in another no pustule at all. In two instances recovery took place without any local or general treatment, and in 26 of the others the caustery had been freely used before admission to hospital, where the only treatment employed was specific serum, and in associated infections, or after separation of the slough, local treatment with Dakin's fluid or carbolic acid solution. The serum used contained 1,500 units in 5 c.cm., and the doses varied according to the severity of the case, sometimes as much as 50 c.cm. being given a day, but the usual dose being 10 to 20 c.cm. The total quantity injected ranged from 10 to 180 c.cm. The intramuscular route was almost always employed, and in urgent cases intravenous injections were given as well. The results of the treatment were very successful, only one death occurring, the patient being a man aged 60, who had been treated for a fortnight before admission in various out-patient departments by local measures. Monteleone's conclusions are as follows: (1) Circumscribed malignant pustule has a tendency to spontaneous recovery. Local treatment often gives rise to a pyogenic infection. (2) Pernicious forms are characterized by oedema, and intermediate forms by a large oedematous zone. (3) As anthrax bacilli are found even at the periphery of the oedematous zone, the action of the caustery is ineffective. Such treatment is indicated only in early cases, in which the pustule can be excised without damage to the surrounding tissues. (4) Specific serum treatment, without fear of large doses, should be employed by preference in severe cases.

215. Radium Therapy in Cancer of the Tongue.

LAYS (*Le Scalpel*, February 4th, 1922) writes hopefully of the modern treatment of cancer of the tongue by radiumuncture. He gives a clear summary of the aims and methods of using radium for the destruction of malignant disease, and points out the tendency to use short-waved rays or their greater penetrating power. He gives a list of various issues showing their sensitiveness to these rays, from the extreme sensitiveness of mycosis fungoides to the very slight sensitiveness of fibrous tissue. The sensitiveness of new growths is related to their histological structure. In the radium puncture treatment needles charged with radium salt are introduced into the tumour and left for seven or eight days. A diphtheroid-looking membranous forams, and after that clears away one may expect good results. It is important to treat any lymphatic infection or enlarged glands as a preliminary. The writer describes the technical methods of measuring and recording the strength of radium emanations used. It should be remembered that new growths become radio-resistant in the course of prolonged treatment, as opposed to normal tissues, which become more sensitive. Hence it is important to give an initial dose of radium strong enough to destroy all the neoplastic cells and to avoid repetition. The writer showed two cases to illustrate the good effects of radium puncture in lingual cancer.

215. Chronic Nephritis and Enlarged Prostate.

LAVENANT (*Arch. des mal. de coeur*, November, 1921) has observed a number of patients who sought advice for enlargement of the prostate, and presented at the same time a cardio-renal syndrome with marked arterial hypertension, dilatation of the left heart, gallop rhythm, and dyspnoea on exertion. Very frequently the cardio-renal symptoms alone attract attention, while the prostatic symptoms escape notice. Potain drew attention many years ago to dilatation of the left heart and gallop rhythm in urethral stricture. These signs are also found in hydronephrosis, polycystic disease of the kidney, and compression of the ureter in pregnancy. Any cause of increased tension in the urinary tract may thus give rise to an increase of blood pressure, and enlarged prostate appears to be the most frequent cause. If the cardiac symptoms are relieved by emptying the bladder with a permanent catheter, an operation is justifiable. Lavenant reports three cases in patients aged 55 years whose hypertension and cardiac symptoms disappeared after prostatectomy.

216. Strained Patella.

UNDER the heading "A hitherto unknown disease of the patella," SINDING-LARSEN (*Norsk. Mag. for Lægevidenskaben*, December, 1921) records two cases examined clinically and by the x-rays. The patients were otherwise healthy girls, aged 10 and 11 years, who, after dancing and jumping, complained of pain in one knee. But though in both cases the disease seemed unilateral on the clinical evidence, the x-rays showed it to be bilateral. The patella was painful on percussion, and in one case the soft tissues over and below the patella were slightly inflamed. Profile skiagrams showed the anterior or lower outlines of the painful patellae to be hazy, and there were abnormal calcium or bone shadows in the soft tissues. The author regards this condition as a periostitis or epiphysitis due to strain, and after about half a year's rest both the clinical and the x-ray signs of disease had vanished. A similar condition was described by Sven Johansson in July, 1921, at the third meeting of the Northern Orthopaedic Association in Helsingfors.

217. Vaccine Therapy in Acute Infections.

KIRKENDALL (*New York Med. Journ.*, January 4th, 1922) points out the value of bacterial vaccine therapy in acute infections, whether as a prophylactic beforehand, or as a therapeutic agent to aid the tissues in overcoming an existing infection. From ten years' experience in the use of mixed vaccines it is claimed that the mortality in pneumonia has been reduced by one-fourth, and, since many cases of laryngeal and pharyngeal diphtheria are complicated with streptococcal and pneumococcal organisms, the use of a mixed vaccine in addition to antitoxin treatment was successful in cases where large doses of antitoxin alone had failed. The indiscriminate removal of tonsils is condemned, and it is urged that treatment should be directed towards aspirating and evacuating pus, wiping out the crypts, and giving vaccines before tonsillectomy is considered. Many swollen and purulent tonsils so treated have given perfect results, and the treatment should be given a trial, resort being had to operation only in those cases which fail to respond. Removal by an expert is advocated. The same principles should govern the treatment of infected conditions of the teeth, by opening the pus pockets and giving vaccines, before resorting to wholesale removal.

OBSTETRICS AND GYNAECOLOGY.

218. Post-Climacteric Adenoma of the Corpus Uteri.

MEYER (*Zentralbl. f. Gynäk.*, January 7th, 1922) describes a condition which he regards as one pathologically and clinically *sui generis*, and clearly to be distinguished from the more common polypus of the corpus uteri. The latter occurs in women who have not yet reached, or have only just passed, the menopause, is single or multiple, invariably arises from the region of the fundus, and as it increases in size is passively driven by uterine contractions through the cervical canal into the vagina. The adenoma to which the writer draws attention is characterized, on the other hand, by its occurrence after—and usually a considerable time after—the menopause as an accompaniment of senile endometrial atrophy, by its developing usually from a lateral situation and filling the cavity uteri by active growth before becoming polypoid, by its somewhat broad pedicle, and by the multiple, cystic cavities which are set beneath and are visible through its mucous covering. The chief clinical importance of such an adenoma is that, by causing post-menopausal haemorrhage, accompanied by uterine enlargement, it is apt to lead to the diagnosis, or at least the suspicion, of cancer of the body of the uterus, or (as in one case associated with coincident fibromata) of a sarcomatous transformation of a myoma. Examination shows senile conformation of the external genitalia, the vagina, and the cervix, together with a soft enlarged uterus with patulous os. Curettage shows an increased size of the cavity uteri, but, owing to the smooth, soft, and yielding nature of the polypoid growth, leads to scraping out of a very small amount of material. Histological examination shows a reduction of the intraglandular supporting tissue and the presence of numerous cystic cavities lined by flattened cylindrical epithelium. Neither histologically nor clinically is there any evidence of malignancy.

219. Re-Infusion of Blood after Rupture of an Extrauterine Pregnancy.

TÜPLER (*Deut. med. Woch.*, January 19th, 1922) records twenty-four cases of ruptured extrauterine pregnancy in which he re-injected into a vein of the arm 150 to 900 c.c.m. of the patient's blood, to which an equal quantity of normal saline solution had been added. None of these cases terminated fatally, and he observed none of the sequels, such as rigors, dyspnoea, cyanosis, drowsiness, restlessness, jaundice, peritonitis, and haemoglobinuria, with which the detractors of this procedure have branded it. He did, indeed, often find the temperature subfebrile after the operation, but this is common after laparotomy for ruptured extrauterine pregnancy, and can therefore hardly be debited to the re-injection of the patient's blood. The author thinks that the addition of the patient's blood to normal saline solution may, in certain cases, save lives that would be lost if normal saline solution only were injected. The rupture occurred in most of his cases in the sixth month of pregnancy, and in nineteen cases the operation was performed within the first twenty-four hours of the rupture. With regard to the technique, no attempt was made to defibrinate the blood nor to add sodium citrate to it. The blood was filtered through eight layers of muslin, and the infusion, which was undertaken by an assistant while the operator was attending to the abdominal field of operation, took from ten to forty minutes. No blocking of the needle by a blood clot was experienced, and the average quantity of blood injected was 520 c.c.m.

220. Renal Glycosuria as an Early Sign of Pregnancy.

ROUBITSCHKE (*Klin. Woch.*, January 28th, 1922) describes a clinical test which he regards as a valuable indication of early pregnancy in cases when the decision is difficult. Frank and Nollmann have shown that by the administration of 100 grams of grape sugar (the stomach being empty) glycosuria was produced in twenty pregnant women (in the third month of pregnancy); but, as in renal glycosuria, the blood sugar was not definitely increased. Nürnberger obtained similar results in 70 cases. The estimation of the blood sugar is necessary to distinguish this puerperal renal glycosuria from other forms of alimentary glycosuria. The tendency to sickness and vomiting produced in pregnant women by such a large quantity of sweet fluid and the high price of the grape sugar are the disadvantages of the tests. It has been shown that after the injection of 1 c.c.m. of adrenalin solution (1 in 1,000), glycosuria only rarely occurs in the normal condition, whilst in pregnancy it occurs frequently. Roubitschke employs a combination of these methods. To avoid any unpleasant effects of the adrenalin injection he employs half the quantity just stated, and to avoid sickness uses only 10 grams of grape sugar and thus also reduces the cost of the test. The test is carried out in the following manner: The

woman takes 200 c.c.m. of tea containing 10 grams of grape sugar (the stomach being empty). After twenty minutes 1/2 c.c.m. of adrenaline solution, 1 in 1,000 (Höchst), is injected. The urine, tested three-quarters of an hour after the injection, and also one hour and fifteen minutes after the injection, always contained grape sugar in 19 of the 20 cases of early pregnancy tested.

221. The Kidney Affections of Pregnancy.

V. FEKETE, FUCHS, and MOLNÁR (*Wien. Archiv. f. inn. Med.*, Bd. iii, 3 Heft, 1922) record the results of their observations in 32 cases of kidney affections during pregnancy. These observations were undertaken (1) to determine the action of a diet deficient in salt and in water on the dropsy in the kidney affections of pregnancy, and (2) to outline more clearly the diagnosis and prognosis of these affections. The detailed observations on the cases are given in tabular form. The authors recognize a group of cases of kidney affection for which no cause can be found except pregnancy. Though the symptoms vary much, two forms may be distinguished. One form is characterized by oedema and retention of sodium chloride and water in the system; but the blood pressure is not raised, the residual nitrogen in the blood serum is not increased, and retinal changes are not found. In the other form prominent features are: nitrogen retention, increased blood pressure, increase of the residual nitrogen, and albuminuric retinitis. In the first form a diet deficient in water and in sodium chloride is of great service. In the second form such a diet is generally useless; and when the retinal changes progress rapidly, usually artificial interruption of pregnancy is necessary, since the retinal changes run parallel with nitrogen retention and increased blood pressure. Amongst 14 cases of eclampsia recorded some presented definite signs of kidney affection (first form), but in others the kidney functions tested showed no abnormal changes. The authors consider that both forms of kidney affection, as well as eclampsia, may be caused by an unknown toxin, and that this toxin in some cases affects only the blood vessels of the subcutaneous cellular tissue (causing oedema without albuminuria), in other cases the kidneys also, in others the kidneys alone, and in others the vessels of the brain only (causing eclampsia); mixed forms are more frequent.

PATHOLOGY.

222. Schistosomiasis and Hepatic Carcinoma.

ALTHOUGH carcinoma is less common amongst South African natives than amongst Europeans, yet statistics show that primary carcinoma of the liver is relatively frequent in South Africans. PIRIE (*Med. Journ. of South Africa*, December, 1921) finds a possible explanation of this peculiar fact in the presence of schistosomiasis. Cirrhosis of the liver is known to be one of the important predisposing causes of carcinoma of that organ, and the deposition of the ova of *Bilharzia haematobium* has been shown by many workers to be a factor in the production of the finer degrees of cirrhosis. Impressed by the accidental finding of bilharzia ova in a carcinomatous liver, Pirie set out to investigate the relationship between schistosomiasis and cancer. Only undoubted cases of primary liver carcinoma were selected, of which 36 were examined, sections of the liver being searched for ova, and the other organs examined for bilharzia infection. In the 36 cases reviewed schistosomiasis was definitely established in 10. In 2 it could be definitely excluded as the result of an exhaustive search. In the remaining 24 information as to the condition of the bladder was lacking, and, although no ova were found in these liver sections, this does not necessarily rule out the possibility of bilharzia infection. Of these 36 cases, 28 were liver-cell carcinoma, 3 bile duct carcinoma, and 5 were regarded as doubtful or mixed liver and duct-cell origin. Schistosomiasis has been shown experimentally to induce a cirrhosis of the liver, and it is believed to be the commonest cause of cirrhosis of the liver amongst the Chinese. The sections examined showed that amongst the South Africans also cirrhosis commonly followed bilharzia infection. This and the actual finding of bilharzia ova constitute strong presumptive evidence for attributing the frequency of primary liver cancer to bilharzia infection.

223. The Wassermann Reaction.

MARTELLI (*Rif. Med.*, November, 19th, 1921) draws attention to the different results obtained by careful, conscientious workers in applying this test, probably due to the qualities of the lipoids and globulins of the antigen and serum used. The way to avoid this discrepancy is to use various antigens and take the mean of the reactions obtained. As to the specificity of the reaction, after

safely relied on if carried out with proper care and on the original lines. One ought to pay more attention to the quantity than to the quality of the phenomenon in the Wassermann test. Other conditions beside syphilis will give the reaction—for example, malaria, but in a minor degree. As to the amount of serum to be used, 0.10 c.c.m. to 0.20 c.c.m. is sufficient, but in doubtful cases it is better to use a larger quantity, 0.40 c.c.m. or 0.5 c.c.m. In latent syphilis a short mercurial or arsenobenzol treatment will often arouse the formation of antibodies, and change the Wassermann reactions from negative to positive. A persistently negative Wassermann with a reactivated serum, if there are no signs and no history of syphilis, may be accepted as definite proof of the absence of that disease.

224. The Bacteriology of Peridental Tissues Radiographically Suggesting Infection.

BERWICK (*Journ. Infect. Dis.*, November, 1921) has made a bacteriological examination of the deep tissues around the teeth in cases which radiographically showed evidence of the presence of chronic alveolar infection. After cleansing the mouth and teeth with an alkaline lotion, he sterilized the area under investigation by means of the topical application of a solution containing 1 per cent. each of brilliant green and crystal violet dissolved in 50 per cent. alcohol. The gum was then incised, and a flap of gum and periosteum laid back with a periosteal elevator. The buccal plate was entered with a chisel and a piece of tissue removed aseptically, and placed direct into a culture medium of glucose broth. Control swabs from the gum just before incision were tested for sterility. Of 71 cultures taken over 10 per cent. remained sterile; in 3 haemolytic streptococci were obtained, in 22 non-haemolytic streptococci, and in 8 staphylococci in pure culture. The remainder showed chiefly a mixture of non-haemolytic streptococci and staphylococci. Amongst the patients were 10 who were suffering from arthritis or neuritis who had been examined for other sources of primary infection, and who had had such sources removed. The effect of removal of the infected teeth in these cases was studied, observation extending over a period varying from sixteen to twenty-five months. In only 2 patients was there any improvement in the condition. From these facts the author concludes that the radiogram is not a reliable indication of the existence of alveolar infection, and that there is no definite evidence to show the presence of a relationship between dental infection and systemic disorder in more than a small percentage of suspected cases.

225. Basal Metabolic Rate.

MEAKINS and DAVIES publish an article (*Edin. Med. Journ.*, vol. xxviii, No. 1, January, 1922) on the significance of the basal metabolic rate. This is defined as the rate of energy exchange during rest when only the essential vital processes are at work. The examination is carried out, before the patient has breakfast in the morning, in a room where there is no noise or disturbance of any kind. The rate of energy exchange is calculated by the method of indirect calorimetry from the analysis of the patient's expired air. The authors describe a new apparatus for this purpose and give full details of the methods for making the calculations. The energy exchange as measured by such examination shows the most marked deviation from the normal in disorders of the thyroid gland, but the internal secretions of the ovaries and the testes also play a considerable part in the rate of exchange. The authors have studied the basal metabolic rate both in hyper- and hypo-thyroidism. In the former they observe that in exophthalmic goitre, although the energy exchange is set at a higher level than normal, yet there are marked remissions and exacerbations. In toxic adenoma no such variations were noted, the basal metabolic rate being uniformly high. On the other hand, in myxoedema the basal metabolic rate is persistently and steadily decreased, whilst with the beneficial administration of thyroid extract it returns. It is suggested that this method of analysis may assist in the making of a more accurate diagnosis of cases with indefinite nervous symptoms which are suspected of being due to disturbances of thyroid function.

226. Complement Fixation Reaction in Tuberculosis.

A SERIES of 50 cases of subacute, chronic, or suspected tuberculosis have been submitted to the complement fixation test by ROUSLACROIX (*C. R. Soc. Biologie*, January 7th, 1922). Besredka's antigen was employed. Though the number of cases is too small to derive any appreciable indication as to the value of the test itself, one interesting point is brought out. Six patients convalescing from encephalitis lethargica, showing the sequelae of tremors, pareses, and disorders of locomotion, all united in giving a positive reaction. In each case the Wassermann reaction was negative. Fortunately an exception of this nature is not calculated to interfere seriously

The Robert Campbell Memorial Oration

ON

THE SURGERY OF THE BLOOD.

BY

THOMAS SINCLAIR, C.B., M.D., F.R.C.S.,

PROFESSOR OF SURGERY IN THE QUEEN'S UNIVERSITY OF BELFAST.

In selecting a theme for this, the first Robert Campbell Memorial Oration, which the trustees have done me the honour of inviting me to deliver, my object has been to find one that would have interest for physicians and surgeons alike rather than one of purely surgical concern, with its wearisome details of minute technique. I trust that in discussing the surgery of the blood, as allusion must be made to various organic diseases of the haemopoietic system, it would be more correct, and more in harmony with medical nomenclature, to regard the blood dyscrasias as secondary phenomena. I hope to justify my presentation of the blood diseases by viewing them from a different angle, and by pleading that the pathology of the anaemias remains obscure.

Cohnheim's conception of the blood as a tissue consisting of cells and a fluid intercellular substance is attractive, and suits my present purpose, although it must be admitted that its cells differ from those of other tissues in their incapacity to multiply and reproduce their like. This conception of the blood raises its dignity from that of a mere circulating medium, a servant to the more stable tissues, carrying to them the materials for their sustenance and renovation, and at the same time doing all the scavenging they require for the smooth performance of their functions. Such adulteration as these menial services imply may appear to detract from its stability and render it unworthy to rank with the fixed tissues as a constructional entity. But the more its characters are studied the more are we impressed with its marvellous capacity for clearing itself and maintaining a relative constancy or homogeneity of composition and structure.

What tissue allows so many liberties to be taken with it and withal retains its vitality and identity? What tissue can vic with it in rapid restoration after haemorrhage, haemolysis in fevers, and other distempers? What other tissue would survive the insults and abuse of injections into it of copious solutions of salt and soda, caustic, mercurial salts, gelatin, gum arabic, ether, alcohol, aniline dyes, and the homologous blood of other persons, whether freshly drawn or bottled and kept in cold storage for a month or more? Still more the injections of vaccines and serums, often in large volume, at the hands of eager bacteriologists and haematologists—as, for example, in the Argentine treatment of anthrax, or in the treatment of pneumonia and tetanus.

Haemophilia.

Nothing has yet been ascertained as to the essential nature of this strange complaint. We do not know wherein consists the defective coagulation, which may take thirty to fifty minutes to accomplish, as compared with the four to five minutes in normal blood when tested by Sir Almroth Wright's method. Must we accept what seems a counsel of despair? or is it a counsel of perfection when non-sentimental engineers forbid the girls of haemophilic families to marry, or, if they marry, to stipulate that they shall not bear children?

It is to confuse operations upon urgent urgency. Can we do for expediency operations, and render these proceedings reasonably safe? Several experiences of my own in this regard make me think that we can. There are degrees of severity in haemophilia, and if we take the milder forms we may test by Wright's process before and again after a few days of preparatory treatment by calcium salts, haemoplastin serum, or repeated small transfusions of homologous blood at short intervals. Even the subcutaneous injection daily of 40 c.c.m. of any mammalian blood, or of human blood not necessarily homologous, may temporarily increase the thrombin elements, and enable us to discriminate those who do not respond, and remain ineligible for operations, from those who do.

Pernicious Anaemia.

In pernicious anaemia the part played by surgery has hitherto been inglorious if we consider the results of splenectomy in the management of the ordinary type; while

in the Addisonian variety the extirpation of the adrenals has been equally unsuccessful. The latest results from the Mayo clinic, however, show some improvement, possibly from improved technique and a careful selection of cases. The Mayo clinic claims now that a couple of years may be added to the life of these patients by a timely splenectomy, combined with transfusions of whole blood carried out after a preparatory treatment by radium, which appears to render the splenectomy much safer. It is doubtful whether the spleen is the seat of the disease, and so accomplished a surgeon as Moynihan, who has recently written so well upon splenic surgery, smugly up to the results, having regard to the risks, do not entitle us to urge this operation upon patients with any degree of earnestness or conviction. The nature of the haemolysis is obscure: it seems probable that it is an infection; yet this has not been established, hence a truly rational handling is denied us, and the treatment remains empirical, with arsenical preparations as the leading agents. The surgical demands in many cases may be limited to transfusions of small quantities of whole blood at ten-day intervals, but these seem little better than retarding, not curative, measures. Large quantities of ox serum alone, which appears to have the advantage over horse serum that it does not sicken, may be considered in promoting thrombokinase formation.

Whether Dr. Hurst's method of grafting adrenal gland tissue into the groin—or, better, into the testis—will stand the test of time remains to be determined, but already some encouraging results have been reported.

Haemorrhage.

Turning next to the management of haemorrhage in normal blood we know that the sudden loss of a fourth part of our thirteen pounds' weight of blood may be fatal; but if the shedding be spread over a week or more by recurrent bleedings prodigious quantities may be lost with ultimate survival. We have been told that the extreme age of a single red blood cell is about one month. The speed with which these cells can be reproduced after haemorrhage is wonderful.

The two important indications in haemorrhage are: to restore the blood pressure by ingesting or transfusing fluids copiously, thus enabling the heart to supply the vital centres in the cephalon with a sufficient quantity of blood, however thinned in quality; and secondly, to maintain the warmth of the body by internal and external means, the latter indication being often overlooked when the mind is intent upon the former. Isotonic saline, or 6 per cent. gum solution, may be employed intravenously, but in extreme cases pure homologous blood should be used if available, and warm fluids given by the mouth or rectum.

I have not been impressed by the results of subcutaneous injections of salines for this purpose; I have noted them unabsorbed after a week, and have frequently seen disastrous sloughing follow their use. Dr. George Rea has recently simplified the determination of the homology of bloods. As to apparatus, we have our choice of the hydrostatic method; the multiple Record syringe method; and the paraffin-lined Kimpton-Brown tube. The technique is not difficult if care be taken not to introduce air bubbles. The direct method of connecting the artery of a donor to the vein of the patient by a ten-inch transparent tube with snitable nozzles, which Mr. Fullerton distinguished himself by introducing, has been found inconvenient, and in septic states of secondary haemorrhage positively dangerous to the donor. For anyone not fully familiar with the technique the safest plan appears to be the reception of the donor's blood into a warm vessel containing one-fifth part of a 3.8 per cent. sodium citrate solution, and instilling this mixture into the patient's veins by the gravitation or hydrostatic method. We must make sure that diseased blood—syphilitic, tuberculous, or malarial—is not used. In this connexion the interesting fact has been discovered that blood from an asthmatic donor has caused asthma in the recipient. Does this in any way show that we may revise our views of the pathology of asthma, and regard it as belonging to the category of blood diseases?

Thrombosis and Embolism.

Are we to assume that clotting of blood in varicose veins and in haemorrhoids in apparently healthy persons is an inflammatory process? It is very difficult to prove that it is so; certainly an attempt to demonstrate microbic activity in such simple cases usually fails. On the other hand, when definite phlebitis or arteritis exists, we can readily understand

that changes in the intima due to inflammation cause thrombosis.

The anxieties in phlegmasia dolens and in veins that have been operated on in various ways are common enough, but why detachment of portions to form emboli should be more frequent in the post-operative states as compared with phlegmasia is not easy to explain. In the recent debate in the Royal Society of Medicine conflicting views were expressed as to whether pulmonary embolism and infarctions were commoner now than formerly. My own impression is that they are on the increase, but to what change in technique or nursing this is to be attributed is not clear. The more recent deliveries from America are to the effect that the limbs should be permitted free movements, and no splints applied after operations on veins, in order to promote a freer circulation of blood. The practice hitherto has been the opposite—namely, to keep the limbs at rest in splints for a long time in order to give time for condensation of thrombi, lest bodily movements should detach portions of soft clots, with disastrous embolic excursions. Similarly, long rest has been enjoined for phlegmasia. A close observation of a number of cases convinces me that embolism is commoner in the cases treated by early movement and activity, and I still remain an advocate of prolonged rest. Likewise, in the treatment of acute thrombosis in varicose veins without operation prolonged rest is best. We have had in recent years a fair number of cases where men have refused to lie up and rest, and a fatal pulmonary embolism has been apparently caused by their activity; it has occurred, also, after the too early dismissal of hospital patients.

From a medical point of view we may discuss two rival and diametrically opposite therapeutic methods. Should we give calcium salts to condense the clots that may have formed, or should we give citrates to render the blood less liable to clot? As a matter of experience citric acid is better than its citrates for the latter object. My own view is in favour of the citric acid scheme as opposed to the calcium salts as a prophylactic against embolism.

If we apply to the physiologists for the reason why coagulation does not take place spontaneously in the blood vessels we are told that thrombin, the activating substance, does not exist in the blood. It has to be formed by the interaction of prothrombin and antithrombin which do exist. When these combine we get the thrombin that can convert the fibrinogen of the blood into fibrin. What the exact catalytic process is whereby the calcium salts and kinases react to liberate the thrombin is not clear.

The substance known as antithrombin appears to be formed in the liver as one of the secretions of the liver cells, and it is added to the blood as it passes through that organ. Now the fluidity of the blood in the hepatic veins as it leaves the liver is much superior to that in the portal system entering it. To facilitate coagulation all that is wanted to inhibit the restraining influence of this antithrombin is some thrombo-kinase, such as is liberated at a wound, bruise, or fracture, or even an internal injury to the intima of a vein, a burst valve, or an overstretch. Antithrombin appears to resemble hirudin, an extract from the salivary glands of the leech, or its more accessible and cheaper substitute albumose of peptone. We do not use this albumose of peptone as a therapeutic agent to prevent clotting because it is a powerful and even dangerous depressor of the blood pressure.

When clotting occurs in a vein after operations, two types of clot are recognized—one the firm white clot at the ligature, and the other a soft red colloidal clot, extending up approximately to the nearest tributary or branch. If the white clot disintegrates, it may be comparatively harmless, for it breaks up into almost powdery fragments. It is the soft red clot we have most to dread. To minimize its formation early movements to reduce stagnation after operations are now recommended. But we may lose as much as we gain by this nursing licence, for, as a soft red clot will inevitably form in some segments, we may by movements facilitate its detachment, leading to embolic developments. It therefore seems to me that the elevation of the limbs, and the foot of the bed, combined with somatic rest, is the safer procedure.

Regarding the matter from the clinical standpoint, we may say that in blood conditions in which thrombosis is the leading feature the coagulability of the blood is already too high. Therefore, in a rational treatment in the prevention of thrombosis and embolism, one would argue that we should endeavour to reduce this tendency by citric acid, or its

citrates, rather than accentuate it by the exhibition of the calcium salts.

The question of the influence of electricity upon thrombosed veins, whether employed as a preventive agent, or to promote absorption or canalization of clots, is interesting. It is well known that the blood of persons killed by lightning remains for a long time uncoagulated, and this has led to the use of electricity in surgery, either as constant current alone or for the ionization of potassium iodide. We learn from Professor Milroy's researches that other influences, apart from the lightning stroke, may account for the fluidity of the blood. Nevertheless, electric ionization over thrombotic areas appears to do good, and to expedite a restoration of the disabled circulation in post-operative conditions. This action, if we admit it, is probably due to a general effect upon the nutrition of the limb as a whole, for we find that the American experience of electrocution of criminals reveals no specific influence upon the coagulability of the blood, either for or against, from electrical currents.

Polycythæmia Vera.

Erythraemia, also called polycythæmia vera, is a rare disease of the plethoric type in which the red cells may rise to double the normal number. This probably depends upon undue activity of the red bone-marrow. Although the spleen is much enlarged, it is a fatal mistake to extirpate the spleen. This organ is not the source of the disease. Rather is it undergoing functional hypertrophy in its efforts to destroy the excess of red blood cells. Forty years ago the spleen was called "the grave of the red blood corpuscles," and in this disease it justifies its old title. Surgery, therefore, directed to the spleen is quite improper. Whether the suggestion of extirpating every alternate rib to reduce the amount of red marrow at work will bring this disease again within the surgical ambit remains to be seen. For the present the best treatment appears to be radium applied to the long bones, or possibly the deep x-ray therapy of the Erlangen school may have some advantages to offer in the future.

The influence of repeated small bleedings in reducing the plethora in erythraemia must also be borne in mind.

Splenic Anaemia or Banti's Disease.

This form of anaemia furnishes a sharp contrast to pernicious anaemia in its curability by early splenectomy before cirrhotic changes in the liver become too far advanced. The operation may, however, be a formidable one by reason of the perioto-visceral adhesions which abound, and bleed freely in their separation. Possibly a preliminary application of radium to reduce the size of the spleen may help to reduce this risk.

Spleno-medullary Leukaemia.

This myelogenous form of splenomegaly—what used to be called splenic leucocythæmia—causes the pendulum to swing strongly from surgery to medicine, seeing that splenectomy in this form has so gloomy a record. The very few patients that have survived the operation have not permanently benefited by it; at most a very brief retardation has followed, but not sufficient to justify so serious an operation. It will be best to depend upon radium, or the intensive deep x-ray application, when the blood count indicates this particular form of leukaemia. Some remarkably good results have been recorded at the Radium Institute.

Lymphatic Leukaemia.

This is a more rapidly fatal disease than the last mentioned spleno-medullary form, and offers even less inducement to surgical enterprise; its hands of the radiologist. It is not so much the increase in size of the lymph glands that strikes one, but the universality of their distribution, rendering surgical extirpation a hopeless task.

Hodgkin's Disease.

On the other hand, Hodgkin's disease reverses this position, and offers in its earlier stages a field for operative surgery. The extirpation of clusters of glands which are very large, discrete, and not adherent through inflammatory changes is not only feasible but useful. The spleen, which enlarges in the later stages, need not be extirpated. At first there are no striking blood changes: the anaemia occurs later on, so that in the early stages the patients are fit to stand operation better than in the anaemias already discussed. Nevertheless, I believe this disease will pass into the hands

the radiologists, and that surgery will be less and less listed in the future for its treatment. The Radium stitute results in this complaint are very encouraging.

Tonsillar Anaemia.

Considerable difference of opinion still exists as to the isdoni of completely extirpating the tonsils, some claiming at an anaemia results from the removal of these haemopoietic organs. There are therefore advocates of the slicing or guillotine operation as against the thorough enucleation. ly own experience leads me to adopt the enucleation plan, as ss liable to be followed by recurrence of the hypertrophy. aside from the primary or recurrent haemorrhage at the ime of operation, which may be copious and account for a emporary marked anaemia, I have not seen a chronic anaemia result after enucleation that would deter me from ablating hese small haemopoietic glands, which are so often removed with manifest advantage to the patient.

Haemolytic Jaundice.

This is a peculiar acholic jaundice, which may be either congenital or acquired, and which may last for years; it is a slow blood disease, with marked anaemia from destruction of red blood cells. In this disease splenectomy has a high curative value, and may arrest the disease quite promptly and satisfactorily.

Purpura Haemorrhagica.

In this disease, hitherto regarded as purely medical, the intervention of surgery is justified, and may prove curative. The spleen is distinctly enlarged, and its removal by splenectomy has been followed by the happiest results. The exact nature of the disease is ill-understood, and why there should be a deficiency of the fibrin-forming elements is not explained. Though apparently not primarily a splenic disease, still the extirpation of the spleen is very useful. In some way it breaks a link in the vicious circle that underlies this malady. Hence a fair field for surgery in this blood disease may be predicted.

Skin Grafting.

Brief reference may be made to important discoveries of interest to practical surgeons in respect to skin grafting. It is desirable before taking grafts, even from a mother to her child, to determine whether the bloods of both harmonize or are homologous. When they do not correspond there may be failure in grafting—a point of special importance when the larger fligths in plastic surgery are attempted.

Blood-letting.

A word must be said about a practice against which the errors and abuses of former generations have created some prejudice. I refer to blood-letting, either local or general. It is more than possible that we abstain from this too often, and that we should reconsider its value. Anyone who has seen the relief afforded by general blood-letting in the congestion of the lungs in immersion cases, and its recent revival in pneumonia, in apoplexy with high temperature and flushed face, will be willing to admit its potency. Similarly, in chronic kidney inflammation, with uraemia imminent, and in polycythemia vera, as I have already mentioned.

Artificial Leucocytosis.

The artificial production of leucocytosis has received some attention since Metchnikoff's experiments showed that the resisting power of the peritoneum against the invasions of virulent organisms could be temporarily increased by injections of sterile broths or peptone solutions. This might be utilized in cases where the surgeon dreaded the onset of sepsis in abdominal operations. The same principle has recently been advocated in the treatment of influenza by the injection into the blood of substances capable of producing a general leucocytosis—for example, nucleinic acid or sodium cinnamate—and favourable results have been claimed for this practice.

In passing these various diseases in review it will be apparent that the account of them is necessarily incomplete and discursive. What will emerge, I think, is this, that surgeons in the future will have to be more thorough physicians and physiologists in order to guard themselves against rash or precipitate extirpations of organs which may be temporarily enlarged and apparently inconvenient burdens. These may not be the seat of the disease, though they may constitute its most conspicuous feature. The enlargement

may actually be salutary—of the nature of a functional hypertrophy to protect the patient—as in polycythemia.

On the other hand, the physicians should see to it that surgical aid should be sought as early as possible after a diagnosis has been made of one of these maladies in which splenic or glandular extirpation has proved of service. In a word, is it not clear that any sharp cleavage between these sister sciences, to which a premature and exclusive specialism is prone, is as unphilosophic as it is unscientific? We should, therefore, condemn an unnatural divorce of surgery and medicine, though both branches must gratefully recognize that only by specialized "team work" in many cases can the necessary diagnosis be laboriously built up.

THE TREATMENT OF INSOMNIA.*

BY

ROBERT DAWSON RUDOLF, M.D.,

PROFESSOR OF THERAPEUTICS IN THE UNIVERSITY OF TORONTO.

THE treatment of cases of insomnia is a very large subject, and here only an outline can be given, founded on an attempt to classify the different forms of the affection under two great heads.

Physiologists cannot tell us exactly what sleep is, and it would serve no useful purpose to enunciate here the different theories—or shall I say hypotheses?—that have been advanced as to its nature. A common belief is that the lowering of blood pressure that undoubtedly occurs during sleep is the cause; but if this were so one should find intense drowsiness in cases of low blood pressure, but this is not usual. Sleeplessness is not a symptom of severe haemorrhage, and, on the other hand, I understand that in mania the blood pressure tends to be low. Again, chloralose is a good hypnotic, and yet it raises the blood pressure. A fall in blood pressure is a usual accompaniment, but probably not the cause of sleep.

Sleep and sleeplessness are associated with decrease or increase respectively in the activity of the cells of the central nervous system, and the cause of this decrease or increase is not always the same. Sleeplessness, indeed, is a symptom and not an entity. One might just as well speak of one kind of cough or one kind of pain as of one kind of insomnia. We see it occur in arterio-sclerosis when the arterial blood pressure may be high, and again in anaemia when it is probably low. Usually a cup of coffee will lead to sleeplessness, but I have known people in whom it has the opposite effect. Evidently the essential cause of the symptom is not the same in the two classes.

Sleeplessness is perhaps the most distressing symptom to which human flesh is heir. Every practitioner knows how it wears out his patients and how a few hours of sleep may alter the whole aspect of a case. Sleep is more essential to life than food, in that an animal may go for weeks without eating, but let it be deprived of sleep for four or five days and life becomes impossible. A form of torture said to have been popular in old days was to deprive the victim of sleep, and it must have ranked high as a producer of exquisite suffering, which was the object of the torment. Our patients sometimes undergo this torture, unless we lessen it by therapeutic means.

As sleep is so essential, it follows that absolute insomnia for any length of time is incompatible with life, and yet often one is told by healthy-looking individuals that they have not closed an eye for weeks. I saw an example of this only the other day. A short period of sleeplessness is, strange to say, productive of an increase in weight of the body, but if the insomnia be persistent a loss of weight ensues, and the degree of emaciation is often an index of some value in estimating the amount of insomnia.

A great many classifications have been made of the different forms of insomnia. Perhaps the one most quoted is that of Germain Sée, which is as follows:

1. Dolorous.
2. Digestive.
3. Cardiac and dyspnoeal.
4. Cerebro-spinal and neurotic.
5. Psychic.
6. Insomnia due to physical fatigue.
7. Genito-urinary.
8. Febrile and auto-toxic.
9. Toxic.

* Communicated to a meeting of the Ontario Neuro-Psychiatric Association, September, 1921.

These nine classes are nine pigeon-holes in which we may put most cases of insomnia, but beyond that they are not of much value, as they are not founded upon any fundamental basis of classification.

Whatever be the ultimate nature of sleep, it appears to me that it depends upon two essential factors, and an increase in either, and especially in both, of these will prevent its occurrence. These two factors are:

1. The degree of irritability of the central nervous system.
2. The amount of afferent impulses reaching the central nervous system.

Table of Causes of Insomnia.

- I. Nervous system hypersensitive, owing to—
 - (a) Inheritance, bad habit, alteration in habits.
 - (b) Fatigue or neurasthenia.
 - (c) Circulatory disturbances, especially arterio-sclerosis and aortic regurgitation.
 - (d) Exciting toxins produced in the alimentary tract or in the body tissues, or introduced from without.
- II. Increase in afferent impulses, as from noise, light, heat, or cold, mental or physical discomfort or pain.

If the irritability of the nerve cells be not abnormal, and if no excessive storm of afferent impulses arrive, then at rhythmic intervals unconsciousness steals over the brain and the individual sleeps, and during that sleep many biochemical changes take place which eventually cause him to awaken with powers renewed for the carrying on of the functions of active life. But let the central nervous system be too irritable from any cause, then, although only the normal amount of afferent stimuli be arriving, these will prove sufficient to prevent sleep; and it is well to remember here that although we may check all evident afferent stimuli, such as light, noise, pain, and so on, during all of life there occurs a constant flow of afferent impulses, which do not normally reach to the level of our consciousness and yet must have a stimulating effect upon the central structures, especially when the excitability of these is raised from any cause. On the other hand, if the degree of irritability of the central nervous system be normal, let the amount of afferent impulses be only sufficient and sleep will be impossible. The most healthy man will be kept awake by an aching tooth or by sufficiently worrying thoughts.

It is easy to put most cases of sleeplessness into one of these two classes, although often a cause may act in both, as when indigestion reflexly causes distress and also increases the irritability by the production of toxins. Looking at See's nine classes it is evident that dolorous, genito-urinary, and psychic cases come into our second group, in that they act by increasing afferent impulses; while those cases labelled cardiac and dyspnoeal, cerebro-spinal and neurotic, fatigue, febrile and auto-toxic, and toxic, act by increasing the irritability of the central cells and hence come in the first group; and lastly, the digestive (and possibly many of the cardiac and dyspnoeal) act in both ways, and hence belong to both classes.

It is manifest that in many patients we are dealing with several causes of sleeplessness, as when we meet with a chronic renal patient who has business worries and who has been imbibing in order to keep himself up to the mark. He has an increased irritability of the central nerve cells due to the toxæmias from the nephritis and the alcohol, and he also has the increase in afferent impulses from the worrying thoughts. An irritable nervous system is being over-stimulated, and of course he cannot sleep.

As regards treatment, an appreciation of the above grouping of the different causes of sleeplessness makes the problem, to me at least, a little less complex.

Although we do not know the essential nature of sleep we do know a great deal about the factors that will favour its occurrence, and on the other hand, those that act in the

By encouraging the former and decreasing the latter as far as possible we can usually, more or less, restore the deranged function.

Speaking generally, in every case we should reduce the flow of afferent impulses to as few as we can, and hence the patient must be placed where light, noise, heat, and cold do not disturb him. Many a sufferer is kept awake by cold feet or other result of an unequalled circulation. Noise keeps most people awake, and yet monotonous noise (like that of the engines of a steamer) may have a soothing effect, and sleeping passengers are usually awakened if the ship stops. Monotonous sound, especially if pleasant and rhythmic, is calming, and hence the value of music in helping the sleepless.

When the afferent impulses are of the nature of pain or discomfort, then we strive to remove the cause of them; but if this be impossible and the centres continue to be stormed by such, then nothing will make these less sensitive to them than opium or its derivatives. But opium is a very edged tool in insomnia, unless this be dependent upon some disturbing condition which is likely to be of short duration, and it has no place in the treatment of chronic insomnia.

If the environment is made conducive to sleep and yet this is wooed in vain, then the central nerve cells are too irritable, and the cause of this irritability must be sought for and if possible removed. Going through our list it is evident that this can often be done. We cannot influence inheritance, but can bad habits, such as the reading of exciting books or indulging in exciting thoughts at night.

When a person is too tired to sleep, a stimulant such as tea or coffee, or even a glass of toddy, may make all the difference. Circulatory disturbances may frequently be treated successfully, as when we use digitalis in cases of auricular fibrillation, and the sleeplessness is thus etiologically treated. In less evident circulatory abnormalities hydropathy is of special value and should always be tried. If the feet are cold a hot bottle may help, or a hot, or even a cold, foot-bath followed by friction may be effectual. A complete warm bath is often valuable, and in very excited cases this may be continued for hours and the patient thus soothed to sleep. I have seen this apparently save life in chorea. Or we may use the wet pack, in which the patient is enveloped in a wet sheet for half an hour and then rubbed dry with a rough towel. The water may be warm, tepid, or cold. Occasionally gentle massage is of value in inducing sleep.

All these physical methods probably act by influencing the circulation. In toxæmia from infections or metabolic changes treatment can often do much; in that due to toxins introduced from without, especially the purin bodies, alcohol and tobacco, the remedy is in our hands.

But in many cases, after all possible afferent stimuli have been checked and all possible causes of irritability of the central cells have been removed, still too much excitement remains, and then, and only then, is it our duty to try and directly lessen this excitement by medicinal means.

Hypnotics should be avoided as much as possible, especially in chronic cases of insomnia, and never used until every other method has been tried. The two bogies that haunt us here are (1) habit formation, and (2) gradual loss of effect, so that the dose of the drug must be constantly increased. But sometimes sleep-producing drugs are necessary, it being wise "to do little wrong to do a great right."

Every practitioner has his favourites here, and I will not weary you with any discussion of hypnotics in general, but will merely say that they should be used as seldom as possible, and in as small doses as will act. They all bring about sleep by dulling the excitability of the nerve centres.

When a hypnotic appears to be required it is wise to begin with the mildest, and here one can put the bromides. They can be given either at bedtime in a single dose of from 30 to 60 grains, or in several doses during the day. It makes little difference what form of bromide is employed. Sometimes a combination of several is preferred.

Next in order may come chloralamide, now official in the B.P. as *Chloral Formamidum*, in doses of 20 to 30 grains, given in solution flavoured with liquorice. Then veronal (dose 5 to 10 grains), and the action of this drug can be enhanced by the addition of an equal amount of aspirin (say 5 grains of each). Then the sulphones, sulphonal and trional, in doses of 10 to 25 grains; and lastly, chloral hydrate, in doses of 10 to 20 grains, repeated. Chloral is rapidly eliminated, and it is better to give it in repeated doses than in one large one, for some people are very susceptible to it, and cases are on record where 30 grains have proved fatal. Often a combination of several hypnotics acts better than a large dose of one. In excited cases paraldehyde in doses of one-half to one drachm is valuable, or we can use hyoscine hypodermically, although occasionally this increases rather than decreases the excitement. An ordinary dose of it hypodermically is 1/150 grain.

Opium should never be used in chronic insomnia, although, as already said, in acute disease, as pneumonia, it is often invaluable.

Some have used hypnotism in producing sleep, but of it I have no personal experience, and in the few cases in which I have seen it tried I have not been much impressed with its value.

SUMMARY.

1. All cases of insomnia may be classified as being produced either by an increase in the excitability of the nerve centres, from an increase in the afferent stimuli reaching those centres, or by both.
2. In every case the afferent stimuli should be reduced as much as possible, and to this end, after the environment has been made as appropriate as practicable, physical therapy, especially hydrotherapy, should be employed.
3. If the excitement of the cerebral centres remain too great, then this may have to be reduced by the employment of hypnotics, and here the mildest should first be used.
4. Opium and its derivatives should never be employed in the treatment of chronic insomnia, or in that dependent upon abnormal mental states.

RICKETS: A THEORY OF THE METABOLIC DISTURBANCES AND OF ITS ASSOCIATION WITH TETANY.

BY

D. NOËL PATON, M.D., F.R.S.

(From the Institute of Physiology, University of Glasgow)

Introduction.

ANY explanation of the etiology and pathology of rickets must take cognizance of the fact that it is not merely a bone disease, but that the symptoms show that there is a profound and general disturbance of the metabolism. The sweating, the muscular weakness, and the close association with the spasmophilic condition all point in this direction. Miss Ferguson¹ found that 43 per cent. of the markedly rachitic and 41 per cent. of the slightly rachitic children examined by her in Glasgow had, or had had, tetany. The slight regenerative change in the muscles, first described by Bug in 1907 and again by Bann² in 1921, with the altered chronaxie recorded by Bourguignon and Bann,³ and the decrease in the creatin content found by Pearl Henderson,⁴ indicate that muscle is implicated as well as bone.

Although the causal factors in the production of the disease are still quite obscure in spite of the immense amount of work which has been done upon the subject, the course of metabolism is beginning to be somewhat better understood. Probably nothing has done more to delay progress than the general acceptance of the belief that a defective supply of calcium to the bones is the basal factor, and the failure to recognize that the decreased ossification may be due to a limitation in the supply in proper form of some other element in bone. While calcium constitutes some 50 per cent. of dried dense bone, phosphoric acid (P_2O_5) constitutes about 40 per cent.

Phosphoric Acid as the Possible Limiting Factor in Ossification in Rickets.

Recent work is pointing more and more to the primary involvement of phosphorus rather than calcium in the perverted metabolism of rickets.

Howland and Marriot⁵ have published a large series of observations on the calcium content of the serum of the blood in rachitic and non-rachitic children showing no marked decrease in the calcium, and more recently Howland and Kramer⁶ give a parallel series showing a marked decrease in the inorganic phosphates. The analyses of Findlay, Noël Paton, and Sharpe⁷ had shown no decrease in the calcium content of the whole blood of rachitic pups, and a series of metabolic studies upon children led them to conclude that the evidence does not point to a primary implication of the metabolism of calcium. The recent work of McCollum and others⁸ shows that a limitation of the phosphates of the food in proportion to the calcium, especially when accompanied by a limitation in the fat-soluble A accessory factor, produces in rats a condition of the bones resembling that in rickets. Some unpublished metabolic studies by Telfer also afford an indication that in rickets there is a decrease in the proportion of the retention of phosphorus to the retention of calcium, as had long ago been maintained by Schabad.⁹

The evidence thus tends to indicate that failure in the supply of phosphoric acid, or its supply in unsuitable form, may be the limiting factor in the ossification in rickets, and this suggests a possible disturbance in the metabolism which

may explain not only the bone changes in rickets but also its association with tetany. This I propose to discuss.

It was formerly supposed that the inorganic matter of bone is composed of some 87 or 88 per cent. of calcium phosphate, with some 10 or 11 per cent. of calcium carbonate, but it is now recognized that the calcic phosphate and carbonate probably occur in a more complex combination, which Gassman¹⁰ considers may be represented by the formula:

The Carriage of Calcium in the Blood.

The very generally accepted theory that the bone salts are carried in the blood in the form in which they are deposited seems to be based upon the older analysis of the relative amounts of calcium and of phosphoric acid in the blood. Since the transference must occur through the plasma, it is the proportion of the two constituents present in this which requires consideration.

The amount of CaO is about 14 mg. per 100 c.cm. plasma. The amount of inorganic P_2O_5 is about 7.2 (Bloor). Hence the amount of calcium is in excess of that which could be carried as $Ca_3(PO_4)_2$, even if none of the inorganic phosphoric acid were combined with sodium and other bases. It has long been found difficult to explain the solution of the calcium in the plasma if it is present as a phosphate, and Hofmeister¹¹ speculates upon the way in which it is held. He considers that it is greater in amount than can exist in simple solution. He discusses the various possibilities, and comes to the conclusion that the colloidal condition of the blood plasma, with its high protein content, renders possible the transport of phosphates, calcium soaps, and lipoids, themselves insoluble in water, in the form of colloidal suspension.

Wells¹² lays stress on the probable action by CO_2 in dissolving lime salts and retaining them in solution, and refers to the work of Barillé, who concludes that calcium is carried in the blood in a definite compound, a "carbon-phosphate" of calcium,

which, on evaporation to dryness, yields about 77 per cent. of $CaHPO_4$, and about 23 per cent. of $CaCO_3$. In an alkaline medium $Ca_3(PO_4)_2$ is formed. Wells points out that 77 parts of the di-calcium phosphate would yield 87.7 parts of tri-calcium phosphate, which is the proportion in bone. Howland and Kramer elaborate this explanation, and point out that "a decrease of the phosphorus (HPO_4) ion would render more difficult the precipitation of tertiary calcium phosphate."

On the other hand, Rona and Takahashi¹³ found that some 20 to 30 per cent. of the calcium of the serum was not diffusible, and MacCallum, Lambert, and Vogel¹⁴ were unable to dialyse all the calcium out of the plasma. Cusby¹⁵ finds that while all the inorganic phosphoric acid may be filtered through a collodion filter, at least one-third of the calcium is retained. Von Meyersburg, Pappenheimer, Zacher, and Murray¹⁶ found that 60 to 70 per cent. of the calcium of serum is diffusible. These facts strongly suggest that the calcium is not all combined with phosphoric acid as assumed by Hofmeister, but that it is in some other combination. Vines¹⁷ gives some evidence that part of the calcium of the blood exists in the ionized and part in the non-ionized condition.

The interesting observations of Paul and Sharpe¹⁸ on the transport of calcium in the blood of the chick, from the liver to the shell, in combination with lower fatty acids, suggests the possibility of its being linked in the blood of mammals to some other substance than phosphoric acid.

Again, the fact that the lime for the bones of the chick comes from the calcium carbonate of the shell of the egg, while the phosphorus for the phosphoric acid comes from the lecithin of the yolk (Plimmer and Scott),¹⁹ suggests that a combination is not formed till the bone is reached. Haines²⁰ describes the abundance of phosphorylated fats in the liver of the chick in the form of isotropic globules during the first two weeks, and finds that during the third week anisotropic globules of cholesterol esters of fatty acids take their place. He suggests that a break-up of the lecithin complex and a recombination of the fatty acids occurs, and that the glycerophosphoric acid, or some other compound, passes on to take part in ossification, while cholesterol takes the place of glycerol in ester combinations with the fatty acids.

Further, the fact that the subcutaneous or intraperitoneal injection of almost any soluble lime salt leads to patches of

calcification in adjacent tissue in which the proportion of calcium to phosphoric acid is the same as in bone seems to indicate a combination of lime and phosphoric acid *in situ*.

In pathological calcification, for example, atheroma, the same proportion exists as in bone, but in the early stages there is a considerable amount of lecithin with cholesterol and fatty acids, and these decrease as the calcification advances, indicating that the phosphoric acid is derived from the lecithin.

The Carriage of Phosphorus in the Blood.

As is well known, the phosphorus of the blood is carried in three definitely distinct compounds: (1) Phospholipin, (2) inorganic phosphorus, (3) nucleic acid. That other combinations exist is indicated by Bloor's²¹ figures. His investigations show that the proportion of the various compounds is more fixed in the corpuscles and that there is a relatively great excess of all these combinations in the corpuscles as compared with the plasma, the distribution of the phosphorus thus being the reverse of that of calcium. The total phosphorus is five to seven times, the lipid phosphorus two to three times, and the inorganic twice as abundant, while an unknown organic compound or compounds is fifty to a hundred times more abundant in the corpuscles than in the plasma. Both in the corpuscles and in the plasma the lipid phosphorus is two to three times as abundant as the inorganic. It is this constituent of the corpuscles which varies. It increases during the absorption of fat, and the possibility is considered that the phosphorus in the unknown compounds may be synthesized with fat in the formation of lecithin. Bloor suggests that the phospholipoids of the plasma may be derived from the breaking down of the corpuscles. He points out that, unless the unknown phosphorus compound can take some part in the exchanges, the small amounts of inorganic phosphates in the corpuscles and in the plasma can play only a small part in acting as a buffer substance. The later analyses of the blood in children by McKellip, de Young, and Bloor²² show comparatively small differences.

Jones and Nye²³ give somewhat similar results, and Bloor's observations are confirmed by the work of Greenwald²⁴ and of Abderhalden.²⁵ Meigs, Blatherwick, and Cary²⁶ give a long series of analyses of the serum of the cow, showing that the variations are considerable, but that generally the lipid phosphorus is in excess of the inorganic. They advance experimental evidence to show that the blood of the udder vein of milking cows contains less phospholipin and more inorganic phosphorus than the arterial blood, and they regard the inorganic phosphates as products of excretion.

The existence of the exchanges of phosphoric acid between corpuscles and plasma somewhat diminished the value of Howland and Kramer's observation that the phosphoric acid of the serum is decreased in rickets, although it may be argued that the serum in rachitic and non-rachitic children was analysed under similar conditions, and that therefore the extent of the interchange was in both cases the same.

Lecithin and Bone Formation.

Lecithin is probably the most abundant phospholipin in the body. Its composition may be indicated as follows:

Glycerol (Fatty acid radicle
(Phosphoric acid—Cholin.

Little is known about the normal metabolism of lecithin in the body. There is satisfactory evidence that it can be formed by the combination of fats, cholin, and inorganic phosphates. This was shown by me to be the case in development of the lecithin of the eggs of the salmon from the water-soluble phosphoric acid of the muscles and by McCollum, Halpin, and Drescher,²⁷ and Fingerling,²⁸ in the formation of lecithin in the eggs of hens and ducks from the inorganic phosphorus of the food. In the chick and in the salmon the phosphates for the bones come from the lecithin of the yolk of the egg, and the constant large amount of lecithin found in the liver during starvation²⁹ suggests that it is in this combination that the phosphorus of wasting tissues is fixed for further use in the body.

The close connexion of the phospholipins with bone formation seems to be indicated by the presence of lecithin before calcification in such pathological changes as atheroma and by the higher proportion of lecithin in the bone marrow of young than of old animals (Gliken,³⁰ Bolle,³¹ Nerking,³² and others).

A consideration of these results seems to point to:

1. The independent carriage of at least part of the calcium and of the phosphorus in the blood to the growing bone as to their combination *in situ*.

2. A limitation in the supply of phosphorus or of phosphoric acid, or a supply in unsuitable form, as the primary disturbance in the metabolism in rickets.

3. The important part played by the phospholipin, especially of lecithin, in the metabolism of phosphorus in the body on its way to the formation of the calcium phosphate in bone.

The possibility is suggested that some modification in the normal metabolism of lecithin may be the essential disturbance in rickets—a disturbance leading to the transference of phosphoric acid to bone in an unsuitable form and to a concomitant change in the metabolism of cholin.

The Metabolism of Cholin and its Significance.

The significance of the cholin part of the lecithin molecule has never been adequately considered by physiologists. It is an ammonia base—

Ethanol tri-methyl ammonium hydroxide.

That it is a substance of considerable physiological activity has long been known. Hunt and Taveau³³ and Dale³⁴ have shown that acetyl-cholin is about 100,000 times as active as cholin, and Magnus³⁵ has given evidence that acetylcholine may occur in the body.

Cholin seems to be excreted from the body only in small quantities (Guggenheim and Loeffler³⁶). Its probable fate has been studied by Reisser,³⁷ who demonstrated an increase in the methyl-guanidin-acetic acid (creatin) in the muscles of rabbits after injection of cholin. Bauman, Hines, and Markham³⁸ perfused cholin in the dog and got an increase in the creatin of the muscles. These observations have been repeated and confirmed in this laboratory by Shanks.³⁹ The toxicity of cholin limited the dose which could be given intravenously and the experiments lasted at most for three hours. The increase of creatin was not constant, but was in many cases distinct, and the average increase fairly corresponded to the increase to be expected upon Reisser's theory.

Burns⁴⁰ had previously shown that during the incubation of the egg of the hen there is an increase in the guanidin which may have been derived from the cholin of the lecithin which is so abundant in the yolk. Thus methyl guanidin,

must be considered as a probable product of the metabolism of cholin.

It is unfortunate that the estimation of methyl guanidin involves a long and complex chemical process. On the other hand, when linked to acetic acid as creatin, it is readily determined by converting it to creatinin and applying Folin's colorimetric test.

Noel Paton, Findlay, and others have shown that methyl guanidin produces the same symptoms as those of tetany, parathyreopriva.⁴¹ It increases the spastic tone of muscle and may produce jerkings and tremors. Burns and Sharp have demonstrated that the amount is markedly increased in the blood and urine of dogs after removal of the parathyroids and in the urine of cases of adult tetany and the idiopathic tetany of children so closely associated with rickets.

The formation of an excess of methyl guanidin in this way from cholin liberated in the metabolism of lecithin would account for the frequent association of tetany with rickets especially if there were any interference with its linkage with acetic acid to form the innocuous creatin.

The fate of methyl guanidin in the body is not fully known, but probably it is not all excreted as such. It suggests that it may first be linked to acetic acid to form creatin, which is an inert substance, and that thus the active guanidin may be detoxicated. The curious relationship between the creatin of muscle to its state of tonus (Pekelharing)⁴² may be due to its formation from methyl guanidin which has so marked an effect on muscular tone. Evidence of this formation has been afforded by Wislart,⁴³ who found that the creatin of the muscles is increased after intravenous injection of guanidin salts.

Conclusion.

The consideration of the evidence suggests that an error in metabolism of lecithin, probably in the liver, may be a causal factor in the failure of bone formation in rickets, and that this faulty metabolism may in some cases be accompanied by an increased conversion of cholin into guanidin compounds, thus explaining the association of tetany with rickets.

The theory is put forward tentatively in the hope that it may indicate lines for further work upon the nature of the disturbance in rickets.

AMPUTATIONS AT THE SHOULDER AND AT THE HIP.*

BY

THE LATE H. LITTLEWOOD, C.M.G., F.R.C.S.ENG.,
Brevet-Colonel R.A.M.C.(T.).

CONSULTING SURGEON TO THE GENERAL INFIRMARY AT LEEDS, AND
FORMERLY PROFESSOR OF SURGERY IN THE UNIVERSITY.

TEN years ago, when I was President of the Leeds and West Riding Medico-Chirurgical Society, I described two new major surgical operations in my presidential address. They were: (1) interseapulo-thoracic amputation, and (2) supra-trochanteric amputation of the femur as a substitute in some cases for amputation at the hip-joint.

My friend and colleague Mr. Lawford Knaggs had already published a short account of the former (*Lancet*, May 7th, 1910), as he was afraid I might delay the publication of the new method and so not get the full credit for my work. It is from his short description that the details of the operation have found their way into the English and American textbooks. The only note of the second operation is in the short report of my presidential address, which appeared in the *BRITISH MEDICAL JOURNAL*, November 4th, 1911.

I had intended to describe these operations with fuller details, and to illustrate the description by the excellent drawings made for me by Miss E. Wright of Leeds, but I delayed doing this, and then mislaid the typescript and the illustrations; they only turned up a few weeks ago. I have lately received letters asking me where my original communications can be found, and am therefore encouraged to believe that the operations are considered to be of some value; this has decided me to place them on record, with fuller details than have yet been published.

I. INTERSEAPULO-THORACIC AMPUTATION.

The operation may be required for trauma and some cases of malignant growth of the upper end of the humerus or scapula. Some have advocated it for malignant disease of

the breast and for extensive tuberculous disease. Professor Berger's name is associated with the usual methods of performing the interseapulo-thoracic amputation. His paper, entitled "L'Amputation du membre supérieur dans la contiguïté du tronc," was published in Paris in 1887. Sir Frederick Treves, Mr. Stanley Boyd, and Mr. (now Sir Gilbert) Barling in this country, and Professor Keen and Dr. La Conte in America, have made valuable suggestions.

Professor Berger was not the first surgeon to perform interseapulo-thoracic amputation, and to speak of the operation I have devised as a modification of Professor Berger's method is not correct. I do not know who was the first to perform the operation, but I remember seeing the late Mr. Christopher Heath remove the forequarter in 1882.

I submit that the operation I perform differs entirely in principle from Professor Berger's; in fact, it has nothing in common with it except the final result—that is, the forequarter is removed. The chief principle in Berger's operation is the ligation of the subclavian vessels as a preliminary step in the amputation; by my method the vessels are secured during the course of the operation. I have only once performed Berger's operation, but I have seen it done two or three times and noticed the difficulties the surgeons experienced in exposing and ligaturing the subclavian vessels; the whole operation took one and a half to two hours. It has sometimes to be done in two stages. I have performed my operation in twenty-five minutes, including the suturing of the flaps. The ease with which the operation can be performed reduces the time and so must be an important factor in the success of these cases.

When the second case presented itself I carefully read up the whole subject again, and, when thinking it over, it struck me that there might be a better way of removing the forequarter than that usually practised. I remembered when I was reading for the first examination for the diploma of F.R.C.S. that I attended a class of special dissections conducted by Professor (now Sir George) Dancey Thane at University College, London. One of the dissections was of the brachial plexus from behind. I think we tried two or three different ways; one was to turn a flap back over the scapula and to divide all the muscles attaching the vertebral border of the scapula to the spine, and I remembered that when this was done the brachial plexus could easily be

seen with the subclavian vessels. It then struck me that this would be a much easier way of doing the operation. So I planned it out on these lines and was delighted with the comparative ease with which it could be performed.

Description of the Operation.

The flaps, of course, may vary according to the exact position of the disease; there are two flaps, a cervico-scapular and a pectoro-axillary.

The patient is placed on the sound side close to the edge of the operating table. A cervico-scapular flap is made, commencing at the clavicle near the outer margin of the sternomastoid attachment, carried along the clavicle over the prominence of the shoulder along the axillary border of the scapula to a point below the angle and backwards to about two inches from the spine (Fig. 1). A flap of skin and subcutaneous tissue is rapidly turned back; this exposes the posterior surface of the scapula, with the muscles attaching it to the spine.

The trapezius and the latissimus dorsi are then divided, next the levator anguli scapulae, the rhomboids, and, lastly, the scapular attachment of the serratus magnus and the omohyoid muscles. Three or four vessels may require ligature, branches of the suprascapular and posterior scapular arteries. The soft tissues are now separated from the clavicle, close to the sternomastoid attachment, and the bone surrounded by a Gigli's saw and divided; the subclavins can now be divided.

The whole upper extremity now falls away from the trunk,

FIG. 1.—A. Line of division of muscles. B. Line of cervico-scapular flap.

* This paper reached us a few days before Mr. Littlewood's lamented death on December 19th, 1921.

held by the subclavian vessels and the cords of the brachial plexus, which are fully on the stretch, standing out and easily seen (Fig. 2).

The cords of the brachial plexus are now divided with a pair of scissors close to the spine; an injection of cocaine into the nerve can be given before division, as has been recommended, to lessen the shock. In my three cases I have not noticed any increase of shock in division of the nerves. I have not injected cocaine.

Clips are applied to the subclavian artery, which is divided

between them; the vein is then seen and treated in the same way. The advantages of securing the artery first have been pointed out by many operators, and in this operation it is the easiest plan. The vessels can now be ligatured, or this can be done after the parts have been removed. The anterior or pectoro-axillary flap is now cut and reflected as far forwards as necessary.

The last stages in the operation consist in the division of the pectoralis major and minor muscles; the position of the division depends on the extent of the muscles it may be thought necessary to remove.

After the division of these muscles the forequarter is removed. This exposes the thoracic boundaries of the axilla and the posterior triangle, so that it is now quite easy to remove any lymphatic glands which require removal (Fig. 3).

The flaps are now sutured and a firm dressing applied. I have recently used silkworm gut prepared with iodine for suturing.

II. AMPUTATION NEAR THE HIP-JOINT (SUPRA-TROCHANTERIC).

The other operation I wish to describe I have called the supratrochanteric amputation of the femur, and I suggest it should be performed in some cases as a substitute for amputation at the hip-joint. I have performed it several times, on the first occasion in 1897.

Amputations at the hip-joint are either done for trauma or for malignant disease of the femur, generally at the lower end, and also for tuberculous disease. The operation here described could not be done for the latter condition, as the disease is in the joint itself.

In cases of sarcoma of the lower end of the femur it is generally taught that the whole bone must be removed. It is unfortunately a very serious disease; in the majority of cases death occurs from secondary deposits in internal organs in eighteen months to two years after the onset; often at a much earlier date. In one of my cases the patient lived five years.

The disease, however, has not in my cases recurred in the stump; the recurrence has generally been in the internal organs, mostly the lung, and in one case I know the death was certified as "tuberculous disease of the lung." I found out that the patient had had several attacks of haemoptysis, due, I have no doubt, to a secondary growth.

I do not believe there is any fear of the growth recurring in the portion of bone—just the head and neck of the

femur—that is left in the supratrochanteric operation. Now the object of my operation is to leave the hip-joint intact, and I submit there is less shock at the time of the operation, and the stump is more useful.

Description of the Operation.

The patient is brought to the edge of the operating table resting on the sound side.

An antero-internal flap is first cut beginning just below the anterior superior spine, coming down to a level to secure an

adequate covering—that is, to one-third of the circumference of the hip-joint—then over the front of the thigh, and upwards on the inner and posterior aspect to a point near the ischial tuberosity; a postero-external flap is now cut. Any flaps that are used for an amputation at the hip-joint would be suitable for this operation. I always think the Furneaux Jordan flap is far too long and bulky, but his principle of keeping the incision away from the perineum should be followed whatever flaps are made.

The inner flap, consisting of skin and subcutaneous tissue, is now

turned up about a couple of inches, the femoral vessels are exposed, clipped with forceps, severed, and ligatured. The muscles are next divided and separated as high as the neck of the femur; the ilio-psoas is the last divided. The branches of the profunda artery are caught in clips, divided and secured by ligatures; with a good assistant the loss of blood is small. The muscles in the outer flap are now divided and separated from the bone, those attached to the great trochanter being severed last. The sciatic nerve is divided after forming this flap. The flaps are held on one side; this exposes the neck of the femur.

The anterior part of the capsule of the hip-joint is attached to the anterior intertrochanteric line, and without opening the hip-joint this must be separated from the neck of the femur upwards for about half an inch by means of a raspator; the neck of the femur is surrounded by a Gigli's saw and the bone sawn through close to the trochanter; the limb is removed, leaving, as will be seen, the hip-joint intact.

The muscles can be brought together with deep sutures and the skin secured with silkworm gut. The stump can be drained if it is thought desirable.

All will agree that it is right to amputate for trauma. Operations for malignant disease are open to criticism. My own feeling is that it is the right thing to do; the fact that one case lived five years is encouraging. Perhaps an earlier diagnosis will give us better results; so often do we wait to see whether the condition is inflammatory, when an exploratory incision would clear up the doubt. During recent years I have explored four cases of enlargements about the lower end of the femur, thinking they might be sarcomatous, and have found them to be due to traumatic periostitis, accompanied by some myositis ossificans. In addition to clearing up the doubt it is good treatment for these conditions, so there is really no reason to delay the exploration, and much time

FIG. 2.—C, Forceps on subclavian muscles. D, Brachial plexus diverted.

FIG. 3.

is gained if, unfortunately, they should turn out to be sarcomatous.

It must be remembered that senry rickets, the result of improper feeding of children, may produce swellings of the lower end of the femur simulating sarcoma.

In my earlier cases I tried to arrest the haemorrhage by means of one of the many methods recommended for amputation at the hip-joint—the names of their originators are not quite legion: Lister, Macewen, Jordan Lloyd, McBurnie, Wyeth, Davies, Lever, and a host of others—the supposed value of these I have delighted to explain to students. They are mainly methods by the use of tourniquets, which are often unsatisfactory; in amputation at the hip-joint some of them may slip over the stump before the vessels have been secured.

I have long given up the use of tourniquets in cases of excisions, as I found that the oozing and bleeding afterwards was considerably less when the tourniquet was not used; in amputations where there is marked arterial disease, and in amputations for gangrene, a tourniquet may do a great deal of damage to the tissues and so favour sloughing of the flaps.

The method for the arrest of haemorrhage used in these cases carries out the same principle as I adopted in the inter-scapulo-thoracic amputation—that is to say, no preliminary attempt is made to control the bleeding, but the main vessels are exposed during the ordinary course of the operation, clipped with forceps, divided, and ligatured.

In ordinary amputations I had never tried this method, until Mr. J. A. Coupland, who was helping me with a supra-trochanteric amputation of the femur, suggested that I should expose and secure the femoral vessels at the point of division in forming my flap. I was a little bit afraid at first of not using some form of tourniquet as a first line of defence against haemorrhage, but was very pleased with the result. It answered admirably, the patient only losing a small quantity of blood. I think this principle should be applied to all amputations. It is not a great deal to expect of any operating surgeon that he should remember the anatomy of the main vessels. If this method is thought worthy of following, then the tourniquet will only be used for first aid.

This method has now been practised and advocated for some time by a certain number of surgeons. I believe, however, that the large majority still rely, as I had done, on the tourniquet.

I find that in a very useful and practical book (*Amputation Stumps*, Oxford War Primers, 1918) the author, Mr. C. Martin Huggins, F.R.C.S., writes (p. 114) in favour of the supra-trochanteric operation in certain cases; the method is also commented on favourably in the *Manual of Surgery*, by Thomson and Miles, 1920, p. 539.

A Post-Graduate Lecture

ON CLINICAL ASPECTS OF ABDOMINAL TUBERCULOSIS.*

BY
JOHN MORLEY, CH.M., F.R.C.S.,

HON.

ASSISTANT
ON FOR
IN

THE great frequency with which tuberculosis attacks the abdomen in childhood, the wide variations in its manifestations, and the grave results to which it often leads, all combine to make it a disease of prime importance in the abdominal surgery of the first two or three decades of life. My purpose in the following remarks is to approach the subject from the point of view of clinical diagnosis, and to state the conclusions to which my own experience has led me on the subject of the appropriate surgical treatment.

Tuberculosis of the Intestine.

Tuberculous ulceration of the intestine in its early stages is a problem for the physician, and rarely, if ever, requires surgical intervention. A history of diarrhoea, accompanied by the passage of some blood and mucus per rectum, is not uncommon in all classes of abdominal tuberculosis, and such a feature in the history gives us evidence of some value, as suggesting earlier tuberculous ulceration of the bowel. It is

only when ulceration has gone on to cicatrization, with stenosis of the intestinal lumen, that the need for surgery arises. Tuberculous ulcers of the bowel commence, as is well known, in the lymphoid tissue of the mucosa, either in the larger collections known as Peyer's patches, or in the solitary follicles, and such ulcers are accordingly commoner in the lower end of the ileum and near the ileo-caecal valve. Two forms of intestinal stenosis are met with in these old tuberculous cases—in one the ulcer, which tends to spread in a circular direction round the lumen of the bowel, gives rise in the process of healing to an annular cicatricial diaphragm. There may be many such stenoses in the small intestine, but not uncommonly they are single. In the second form there is a massive formation of fibrous tissue, which gives rise to a gross thickening of the intestinal wall, as well as a narrowing of its lumen. I will illustrate these types by two cases:

CASE I.

A woman, aged 36, on whom I had operated eighteen months before for tuberculous wrist with a very satisfactory result, returned to hospital complaining that for the past twelve months she had suffered from intermittent attacks of acute pain in the left of the epigastrium. These attacks had occurred with increasing frequency, until they came on every week, and were accompanied by vomiting. There was no history of jaundice. On examination the upper abdomen was somewhat fuller than normal, but no palpable mass could be detected, and there was no visible peristalsis. There was no localized tenderness in any part of the abdomen, and x-ray examination was negative. In view of the nature of the attacks and the previous tuberculous lesion, the provisional diagnosis of tuberculous stricture of the intestine was made, and exploratory laparotomy undertaken. On examining the small intestine systematically a single annular, fibrous constriction was found in the jejunum some two feet below the duodeno-jejunal flexure. On the peritoneal coat of the bowel there were several small grey tubercles, and there was some enlargement of the mesenteric glands in the neighbourhood. The bowel above the stricture was somewhat hypertrophied and distended as compared with that below. Four inches of jejunum were excised, including the stricture, and lateral anastomosis performed. The patient made a rapid recovery, had no more attacks of pain, and when last heard of was in good health. Histological examination confirmed the diagnosis of tuberculous ulceration.

CASE II.

A woman, aged 29, had for five years been suffering from attacks of pain in the right iliac fossa, associated with local tenderness, vomiting, and increasing constipation. Her general health was poor, and she had lost a good deal of weight. On examination the right iliac fossa was found to contain a firm, palpable mobile mass, somewhat tender on pressure. There was no general abdominal distension. The diagnosis lay between ileo-caecal tuberculosis and carcinoma of the ileo-caecal valve. On exploring the abdomen the lower eight inches of the ileum, the ileo-caecal valve, and the caecum were found to be involved in a uniform hard and massive thickening, which strongly resembled a carcinomatous growth. On the peritoneal aspect, however, numerous small white tubercles could be made out. Lateral anastomosis between the normal ileum above and the transverse colon, combined with resection of the diseased area of bowel, brought speedy relief to her symptoms, and when seen recently, five years after the operation, she was in good health.

When such cases of hyperplastic ileo-caecal tuberculosis are met with in young children, they must be diagnosed from chronic intussusception or appendicitis with abscess formation. In chronic intussusception the attacks of pain are much more frequent and urgent, there is usually some passage of blood-stained mucus, and the illness is rarely of more than a few weeks' duration. In acute appendicitis with abscess formation there is again a much shorter history, with a typical sudden onset, and the mass is firmly fixed and not movable as in the case under discussion.

In older patients the diagnosis from carcinoma is a matter of extreme difficulty on account of the similarity of symptoms. In some cases the presence of subperitoneal tubercles will determine the diagnosis at operation, though even these may not be distinguishable from secondary carcinomatous nodules, and it may sometimes happen that the diagnosis between hypertrophic tubercle and carcinoma of the ileo-caecal valve remains in doubt until the specimen has been submitted to microscopical examination.

Tuberculosis of the Appendix.

Tuberculosis of the appendix, as an isolated lesion, is an occurrence of some rarity. The majority of recorded cases of tuberculous appendicitis have occurred in combination with hyperplastic ileo-caecal tuberculosis, and in such cases implication of the appendix in the tuberculous process must be regarded as a comparatively unimportant detail. The following case of primary tuberculosis of the appendix is the only one that has come under my care.

* Delivered at St. Mary's Hospital, Manchester.

CASE III.

A boy, aged 7, had had a brief attack of abdominal pain and pyrexia two years before he was brought to me with a history of two days' pain that began in the umbilical region and had settled in the right iliac fossa. He had not vomited, and his temperature and pulse were normal. On examination the boy did not look ill, but on palpation in the right iliac fossa there was a definite hard, tender mass, which felt much like an acutely swollen appendix with surrounding omental adhesions. The mass was, however, better defined and more mobile than usual, and there was little muscular rigidity.

A diagnosis of acute appendicitis was made, and laparotomy disclosed a hard, elongated mass lying below and to the inner side of the caecum. The mass was 4 in. long and 1 in. in diameter, and the omentum was adherent to its lower extremity. It was readily delivered through the abdominal wound, and proved to be an appendix, enormously distended and congested and twisted somewhat on its origin from the caecum. The adherent omentum was ligatured off and divided, without stripping it from the appendix; the appendix was removed by dividing it across at the healthy base, and the stump invaginated in the usual way. Examination of the specimen showed that the distal half was involved in typical hyperplastic tuberculosis, with areas of caseation here and there. The lumen of this distal half was reduced in size, but the proximal half, with thin and non-tuberculous wall, was distended with blood pus, and the outlet into the caecum was blocked by a hard secretion. It was evidently, therefore, a case of acute obstructive inflammation of the appendix, superimposed on a chronic tuberculosis, which had given rise to no symptoms. The ileo-caecal junction and adjacent glands were not tuberculous. The boy made an uneventful recovery, and is now, five years after the operation, in good health.

Tuberculosis of the Liver.

Tuberculosis of the liver is also a rare occurrence in surgical practice. Setting aside the cases in which the liver is involved in general miliary tuberculosis, tuberculous peritonitis, or multiple small tuberculous abscesses, cases are occasionally met with in which a solitary tuberculous mass is found in the liver and can be removed by operation. That the diagnosis of such a tuberculoma of the liver is by no means simple is illustrated by the following case.

CASE IV.

A boy of 13, who had been operated on a year previously for "tuberculous glands of the neck," came to hospital complaining of abdominal pain. On palpation a rounded, hard lump, about one inch in diameter, could be felt, and indeed seen, in the right epigastrium. It was evidently in the right lobe of the liver, and in view of his previous history the diagnosis of tuberculosis of the liver was made.

On opening the abdomen a solid yellow mass was found on the anterior aspect of the right lobe, with a smaller adjacent mass of a similar character. Both these masses were enucleated with ease, but it was noticed that instead of presenting the homogeneous appearance of caseating tubercles, they were somewhat lamellated and the appearance suggested gumma.

A Wassermann reaction taken after the operation was strongly positive, and histological examination of some of the excised tissue confirmed the diagnosis of gumma. It is quite possible that the supposed tuberculous glands that had been previously dealt with had, in reality, been the result of congenital syphilis.

Tuberculosis of the Mesenteric Glands.

I now pass to the consideration of the commonest form of abdominal tuberculosis—namely, tuberculosis of the mesenteric glands, and in this group of cases I do not include those with general tuberculous peritonitis in addition. The diagnosis of tuberculous mesenteric glands in children is by no means difficult, for it may be laid down as a broad general rule to which there are few exceptions, that wherever a child presents a firm, rounded, mobile lump in the umbilical or right iliac zones of the abdomen, unassociated with intestinal obstruction, the case is one of tuberculous adenitis. Surgical interference is necessarily limited to those cases in which the glandular implication is not too extensive. Where the whole chain of mesenteric glands is grossly enlarged and caseous, any attempt to excise them would endanger the blood supply of the bowel, to say nothing of the risk of lighting up tuberculous peritonitis. There is, however, a very common type of case in which one or two glands, lying along the ileo-colic vessels in the angle between the lower ileum and the ascending colon, are enlarged and caseous. These glands receive the efferent lymphatics from the appendix and ileo-caecal valve, and their infection with tuberculosis is closely analogous to the common tuberculous adenitis of the upper deep cervical glands which receive the drainage of the tonsils. I have frequently removed the appendix and the glands in such cases, but have never yet, on microscopical examination,

found any evidence of tuberculous disease of the appendix, though typical tubercle formation can usually be found in the glands. In the case of tonsils which are removed in association with tuberculous cervical glands, we know that under 5 per cent. of such tonsils show tuberculous lesions. I believe that in the appendix, as in the tonsil, a chronic catarrhal inflammation of the lymphoid tissue, of a non-specific nature, acts as a predisposing cause to tuberculosis of the glands, and that the tubercle bacillus can be absorbed through the mucosa of either a normal or chronically inflamed appendix and give rise to no specific lesion until it reaches the nearest lymph glands.

What, then, are the indications for surgical interference in these cases? I believe operation should be undertaken if, after a few weeks' constitutional treatment, the glands do not disappear, provided that the glandular swellings are not too extensive. I believe further that if recurrent attacks of colicky pain are associated with glandular enlargement operation should be advised in any case, for such pains signify some mechanical interference, by kinking or adhesions, or perhaps by an associated stenosis, with the peristaltic movement of the bowel.

CASE V.

A girl, aged 7, was brought to hospital with a history of repeated attacks of abdominal pain, accompanied by vomiting, during the previous six months. The child was thin, and the abdomen somewhat distended; on the left of the umbilicus an indefinite hard mass could be made out on palpation. Laparotomy disclosed a mass of caseous glands in the upper mesentery adherent to the transverse colon and kinking it somewhat acutely. The glands were freed from the colon and excised, and an omental graft placed over the area of colon denuded of peritoneum. Since this operation was performed, nearly a year ago, the child has been free from the attacks of pain, and has put on weight.

Occasionally, as is well known, such isolated tuberculous glands will produce a kink of the adherent bowel sufficiently grave to cause acute intestinal obstruction, and I have records of one case in which gangrene of the apex of an adherent intestinal loop had resulted, and necessitated resection of the bowel. The cord-like adhesions so prone to result from tuberculous mesenteric glands in childhood are, of course, one of the commonest causes of acute intestinal obstruction in adult life.

Tuberculous Peritonitis.

In considering the subject of tuberculous peritonitis I would first remark that whereas, according to *post-mortem* statistics, this disease is most common between the ages of 30 and 40 years, according to my clinical experience it is most usually met with between the third and twelfth years of age. We can distinguish broadly two main clinical groups of tuberculous peritonitis:

1. The *ascitic* type, in which the whole peritoneum is distended over with innumerable tubercles, varying in size from the finest grey granules to discrete yellow nodules almost as large as a pea. In this type adhesions, if present at all, are unimportant in number and extent, and a massive ascites dominates the clinical picture.

2. The *plastic* type, with a large, doughy abdomen, in which tympanites is more evident than ascitic fluid. In this second form there are often localized pockets of clear fluid, but the outstanding feature is universal adhesions, fibrous in character, which often obliterate the peritoneal cavity almost completely. In the graver cases of this group large caseating tubercles are found between adjacent and adherent coils of intestine, and in some, though this is infrequent, definite abscess formation occurs.

These two clinical groups have this in common, that the child's abdomen swells, and at the same time there is wasting of the limbs and face and marked failing in energy; but, whereas in the ascitic type there is shifting dullness in the flanks and a fluid thrill, in the plastic form these latter signs are absent, and there are commonly palpable masses of adherent, infiltrated omentum, with considerable enlargement of the mesenteric glands. Symptoms of associated tuberculous ulceration of the intestine are uncommon in each type in my experience, though there is not infrequently a previous history of blood-stained diarrhoea. Pain is unusual in the ascitic form, and may or may not be present in the plastic.

It has long been recognized that laparotomy gives the most satisfactory results in the ascitic form. To what mechanism we should attribute the remarkable improvement that occurs in most of these cases from the day of operation is a problem on which many theories have been

elaborated, and concerning which little definite is known, but this improvement is an undoubted clinical fact. It is not to be denied, of course, that certain of these cases make a complete recovery under medical treatment without surgical assistance, but the change in their condition after laparotomy and evacuation of the ascitic fluid is so rapid and so striking that there is, I think, no doubt that operation has a most definite influence on the course of the disease.

CASE VI.

A girl of 14, who had had no previous ill health, was playing hockey for her school team when she noticed an unwonted shortness of breath. Seven days later, when I saw her, there was a large collection of ascitic fluid, without any pain, and her limbs were already wasting. Operation, performed three days later, showed tubercles so profusely scattered all through the peritoneal cavity as to be confluent, with great thickening of the peritoneum itself, but no adhesions. When seen eight months after the operation she had put on over 25 lb. in weight, the abdomen was normal, and she appeared to be in every respect a healthy girl.

The abdominal incision should always be sutured in layers without drainage, on account of the danger of mixed infection and the greatest care should be taken to prevent tuberculous infection of the abdominal wall—a not uncommon complication which is a cause of serious delay in convalescence.

The prognosis after laparotomy in the plastic type of tuberculous peritonitis is generally considered to be poor, and it is undoubtedly a fact that the percentage of recoveries is smaller in this than in the ascitic type, whether treated by medical or surgical measures. There is the further consideration that laparotomy in these cases is by no means devoid of risk, since the intestines are firmly adherent to the abdominal wall and to adjacent coils, and unless the greatest care is exercised by the surgeon, a faecal fistula may readily be produced, with disastrous results. I was somewhat surprised to find, however, on tracing a series of eight of these cases in which I had operated as a last resort, that five of them, in spite of the very grave prognosis that I had given on the strength of the operative findings, were in good health after four, seven, one, two and a half, and two years respectively, and all dated improvement from the operation. One patient had made such a rapid and complete recovery as to be on active service in Mesopotamia for two years without any ill health. Of the remaining three cases, one improved for a time, but died of bronchopneumonia one year after operation, one is suffering from pulmonary phthisis and still has abdominal pains and distension, and one developed a faecal fistula shortly after the operation and died in about three weeks. The series is, of course, too small for any wide conclusions, but it does at least suggest that there is something to be gained in these cases by surgical measures when medical treatment has failed.

CONCLUSIONS.

I would sum up the general indications for operation in the various types of abdominal tuberculosis as follows:

Pain, when it occurs in recurrent, well-defined, colicky attacks, especially if they return with regular periodicity and sharp intensity, signifies a mechanical interference with intestinal peristalsis, and this can only be relieved by operative measures.

Glandular masses in the mesentery, if not too extensive, and if they do not yield rapidly to constitutional treatment, should be excised, and this is particularly urgent when they are associated with colicky attacks of pain.

Palpable masses in the ileo-caecal region associated with signs of chronic intestinal obstruction are an emphatic indication for laparotomy and resection of the tuberculous ileo-caecal region should such be found.

The ascitic form of tuberculous peritonitis is essentially a disease for surgical treatment. The operation is free from danger, and its beneficial results are usually dramatic. I need hardly labour the point that the utmost care in the medical or constitutional treatment is of great importance in the cure, but I wish to emphasize the view that operation is almost equally essential.

Finally, in the plastic type of tuberculous peritonitis, if the trouble does not yield to the ordinary medical measures, operation may be undertaken with a fair degree of safety, provided that no extensive attempt is made to separate adhesions, and there is some ground for hoping that even these apparently desperate cases may make a complete recovery.

OBSERVATIONS ON THE RESTING METABOLISM OF CHILDREN AND ADULTS IN SWITZERLAND..

BY

LEONARD HILL, AND J. ARGYLL CAMPBELL,
M.B., F.R.S., M.D.

With the Co-operation of
BERNARD HUDSON, M.D.

We have carried out observations at the English sanatorium in Montana, in November and December, where the patients are under the supervision of Dr. B. Hudson, and where a laboratory and every assistance in our work was given us. We also made observations at the Belgian children's clinic under Dr. Chassot, and the Geneva sanatorium under Dr. Betchow, and we are greatly indebted to these physicians for the facilities they afforded us.

In October the sunshine at Montana averaged over eight hours a day, and during the last three weeks of November the sun shone every day, while the air was calm and frosty; the thermometer, while showing from 5° to 20° F. of frost at night, rose at midday in front of the sanatorium to some 50° F. dry bulb and 35° F. wet bulb. Montana is at an altitude over 5,000 ft., and the midday winter sun piercing the clear atmosphere was so warm that it raised the surface temperature of a dark fur or wool coat to 100° or 122° F., and no shade became necessary for the head.

While the sunlight absorbed by the clothes and skin warms those parts of the body exposed to it, the shaded parts of the body are actively and pleasantly cooled by the cool dry air, and the heat production of the body is thus stimulated. In the shade, or before the rising and after the setting of the sun, the cold dry air stimulates the body heat production far more powerfully. Patients can sit or lie out of doors in the sun in comfort, even without overcoats, after 9 a.m., when the temperature of the air is scarcely above the freezing point. In sheltered sun-boxes, open only to the south, they can comfortably expose themselves nude to the sun. Such exposure has, of course, to be gradually inducted, and, while suitable for surgical tuberculosis, is considered unsuitable for phthisis. We suggest that, given a sufficiently high cooling power of the air, insolation might be borne by such cases when not febrile. Such is the experience of Rollier at Leysin. It is obviously unwise to produce tissue cell degradation in the skin or blood by exposure to the sun when the body is dealing with an active tuberculous process and is febrile.

At an altitude of 5,000 ft. the greater tenuity of the air not only stimulates red blood formation, but the breathing, and the greater volume breathed of dry cool air acts with advantage on the respiratory membrane, for the amount of water vapour evaporated daily from this membrane may be some three times greater in patients taking exercise in the Alpine winter climate than in people living a sedentary life in England indoors, where the water vapour tension is much higher. Saturated air at 0° C. holds some 5 grams of water vapour per cubic metre, while air saturated at almost body temperature holds some 40 grams. The dry cool air as breathed in is warmed up to almost body temperature and saturated with water evaporated at this temperature from the breathing passages. The greater evaporation of water entails a greater flow of arterial blood and lymph through the respiratory membrane, and this helps to keep up its health and immunity to disease.

The cooling power which the Alpine air exerts out of doors on a dry surface at body temperature, as measured by the kata-thermometer, is some three times greater than in ordinary conditions indoors, and the evaporative power twice as great. The heat production of the resting subject, stimulated by this cooling power, is put up, above that taken indoors in London, some 40 to 50 per cent. in the case of clothed adults, and 60 to 90 per cent. in the case of children exposed more or less nude to the sunny, calm Alpine winter atmosphere. A cold wind and cloudy sky may raise the breathing metabolism of clothed children over 200 per cent. Increased appetite, better digestion, and more active breathing and circulation of the blood result from this increased heat production. Owing to the climatic conditions the growth of muscular tissue is enhanced and fatness and flabbiness opposed. For early cases of phthisis and all cases of surgical tuberculosis, then, the Alpine winter climate offers great advantages.

* Millicalories per sq. cm. per sec.

We employed the Douglas-Haldane method of indirect calorimetry, the subject lying quiet for half an hour before the sample was taken. Table I shows the results obtained from boys and girls under 16 years of age suffering mainly from surgical tuberculosis. The calories per diem found may be compared with the basal standards of Benedict and Talbot¹ for the same weight. It will be noted that the calories found show increases varying from 59 to 225 per cent. above the basal. The standard figures for the weights of healthy children of the same age are also given. In some cases our subjects were under-nourished, but others gave better figures for weight than the standards, so that under-nutrition cannot play a great part in the increase noted. Blunt and others² find that under-nourished children give higher figures for calories per diem than normal children. We consider that the increase in metabolism was due to exposure to the high cooling power of the atmosphere. The Belgian children on the balcony were partially nude and exposed on sunny days, calm or with very

standards we have taken the basal to be 40 calories per sq. m. per hour for men, and 35 calories per sq. m. per hour for women. It will be observed that in all cases the metabolism was above the basal, the increase varying from 38 per cent. to 79 per cent.

All these observations were taken two or three hours after breakfast, so that the influence of food must be considered. However, in many cases the breakfast was the small continental meal, and this does not increase the metabolism. taken three hours after it, more than 2 per cent. (Du Bois). A large breakfast would not account for more than 20 per cent. increase. Here again we consider that the main cause for the rise in metabolism was the exposure to the higher atmospheric cooling power. None of the phthisis cases submitted their bodies to insolation. They rested on couches fully clothed, and, as a rule, shaded the head. They took exercise before the midday heat of the sun, and after when the sun was down. The pine woods provided plentiful shade

gentle breeze. The children in the shelters were clothed, but exposed on a cloudy day to a very cold wind—so cold was it that the children's pulse could not be felt at the wrist owing to vaso-constriction, and one had to listen to the heart. The Geneva children were clothed. Slight shivering was obvious in some cases. On some days the children were more exposed than on others, but in any case were exposed to a much higher cooling power than children enclosed in a calorimeter chamber, such as that used by Benedict and Talbot. One would expect, therefore, a much higher degree of tone under the former conditions than the latter. The children at Alton Hospital, Hampshire, gave an increase of 40 to 50 per cent. above basal by exposure to open air in the summer and 130 per cent. in the winter, but the children at Alton were never exposed so much as to allow shivering. The Alton summer figures are not much less than the Montana winter figures taken on calm sunny days. The children at Hayling Island undergoing sea-bathing show figures as high as those given by the clothed children exposed to a cold wind on a cloudy day at Montana. The body metabolism can, then, be excited by exposure and bathing in Southern English summer to the same degree as by exposure to the winter Alpine climate.

Table II gives the results obtained from adults, some of whom were healthy and others suffering from phthisis. For

for the morning walk. The serious cases of phthisis—those confined to bed—were not exposed to insolation, but were able to derive benefit from exposure to Alpine conditions of open air, and showed no less an elevation of metabolism. The metabolism of the more serious cases must rise to meet the cooling power to which the patients are exposed, otherwise their body temperature will fall and they will require protection by shut windows, more clothing, and artificial heat. It is obvious that those cases will benefit from exposure which can respond to it by adequate increased metabolism and digestion and absorption of food. Thus, Sir Henry Gairdner finds that the sea air at Hayling Island is too strong for weakly young children, and they do better at Alton. Their surface exposure is too great in proportion to their body mass. On the other hand, stronger, heavier children do better at Hayling Island. Open-air treatment requires to be controlled by exact measurements and good sense. The sunshine and calm frosty air of the Alpine winter make the management of open-air treatment comparatively easy, and its effect on the feelings of the patients hastens their response.

The accompanying tables show the average results of our observations.

ERTUSSIS WITH A LEUCOCYTOSIS OF 176,000.*

BY
GEOFFREY BOURNE, AND J. M. SCOTT,
M.D., M.R.C.P., B.A.

This case is reported for two reasons. No other white blood count of such a high figure (176,000) has come to the notice of the writers, excluding those found in leukaemia. It is hoped that publication of such a leucocytosis in connexion with a case of whooping-cough may arouse speculation as to the possible reasons for its coexistence with this disease.

The patient, a female child aged 1 year and 9 months, was admitted to St. Bartholomew's Hospital under the care of Dr. Hugh Threshfield, to whose kindness the writers are much indebted for permission to publish the particulars of the case. The child was admitted with fever (102°), dyspnoea, and tachypnoea (rate 60), and with signs of bronchopneumonia in both lungs, especially the right: an ulcer was present on the frænum linguae.

History of the Condition.—For the preceding twelve days the child had been subject to fits of coughing of gradually increasing severity and duration. During the later attacks she was alleged to have become blue in the face. The cough was paroxysmal and composed of numerous successive expiratory efforts. No whoop had been heard. The attacks were followed by vomiting.

Course.—Fever, tachycardia, and tachypnoea persisted for six weeks, during which time the pulmonary signs gradually cleared up. The child was discharged after a stay in hospital of seven weeks and an illness of nine weeks' duration.

Blood Counts.

The first white blood count was taken on November 28th, the sixteenth day of the disease: it showed 176,000 white cells per cubic millimetre, of which 116,000 were lymphocytes; the dates of the successive counts are shown in the chart. The black line in the diagram represents the total white blood count, the divided line the number of lymphocytes, and the dotted line that of polymorphonuclear cells.

In connexion with the high lymphocytosis observed, it is interesting to compare the results of two German observers.

Reiche¹ reports an outbreak of influenza in a ward devoted to whooping-cough. He says that 8 of the 16 cases already in the ward were attacked by influenza, and that one in the early stages of both diseases was admitted soon after. The latter case had a white count of 172,000—a figure nearly identical with that noted in the case herein described. He would seem to think that the mixing of the infections was the reason for the high figure. The explanation would be applicable to this case, seeing that it undoubtedly occurred early in the present epidemic of influenza. All evidence, however, is valueless while the cause of influenza is yet unproved.

Hess² of Frankfurt alleges that the lymphocytosis of whooping-cough is the direct mechanical result of the paroxysms; he has made numerous blood examinations, and states that the lymphocytosis is greatest in the paroxysmal stage—indeed, that the highest figures actually coexist with the height of the paroxysms themselves. He suggests that the paroxysms, by increasing intra-abdominal pressure, squeeze lymphocytes out from the spleen and the thoracic duct into the circulation.

The present case also seems to show that the lymphocytosis is high at the end of the paroxysmal stage. Clinically, although the white count fell from November 28th till December 9th, no improvement was obvious. That this fall in the count was of good prognostic significance is suggested by the fact that from the latter date improvement was pro-

gressive. It is interesting to observe that the excessive lymphocytosis—presumably a manifestation of active pertussis—was present sixteen days after the onset of the disease.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

REACTION TO TREATMENT BY KLEBS LOEFFLER'S BACILLUS VACCINE.

WHEN so much is being written for and against vaccine therapy the following account of a case under treatment in hospital may be of interest, especially as one has read a lot concerning the freedom from reaction of patients who have been treated by certain types of vaccine.

In February, 1921, a patient, aged 18 years, was admitted to the diphtheria block of this hospital as a case of faucial diphtheria. Microscopical investigation showed that this was indeed the case, and the usual treatment was given, including antitoxin, and the patient was discharged on March 3rd, after an uneventful recovery. On November 4th she complained of sore throat, and a swab having been taken by her doctor and examined by me, the Klebs-Loeffler bacillus was found. On admission to hospital her tonsils were found to be dotted over with pieces of membrane, the constitutional disturbance of the patient being very slight. No antitoxin was given, and from inquiries into the history the case was looked upon as one in which the diphtheria bacillus had been lurking in the tonsils and throat. A course of vaccine treatment was begun, the ordinary stock vaccine being used (strength: 1 c.cm. = 50,000,000 organisms). I began by giving 0.5 c.cm., and the list below shows the dates of administration, dosage, temperature, and pulse rates:

Date.	Dose.	Temperature.	Pulse Rate.
Nov. 5	0.5 c.cm.	93.2°	72
" 9	0.75 "	93.6°	90
" 13	1.0 "	97.6°	80
" 17	1.0 "	93°	80
" 18	nil	99°	86
" 19	—	93.2°	88
" 20	—	99.6°	93
" 21	—	100.6°	93
" 22	—	101°	96
" 23	—	101°	100
" 24	—	101°	95
" 25	—	100.4°	95
" 26	—	99.6°	83
" 27	—	93.2°	80

On November 18th, the day following the final injection, which was given in the right arm, a localized swelling and tenderness were present at the site of injection. On the 21st the left arm and forearm became almost covered with raised, red, erythematous-looking spots, which varied in size from 2 by 2 inches to 1½ by 1½ inch. They were exceedingly painful, gradually increased in size, and many became confluent, forming large, inflamed patches, darkish beneath. The right arm appeared of a very 25th a similar eruption appeared on both legs, the spots being again painful and exquisitely tender to the touch. The patient complained of pains in the elbow and also in the knee joints, and the general condition was alarming. On the 27th the temperature dropped, and the pain in arms and legs disappeared. The many patches on the arms and legs began gradually to fade, but in disappearing they passed through exactly the colour changes which a traumatic extravasation of blood undergoes in the tissues.

At present, with the exception of dark staining on the arms and legs, the patient feels quite well. The Klebs-Loeffler bacilli have disappeared from the throat.

I am much indebted to the M.O.H. for Brighton, Dr. Duocan Forbes, through whose courtesy I am enabled to publish this case.

DANIEL HUGHES, M.B., B.Ch., B.A.O.,
Resident Medical Officer, Sanatorium and Infectious Diseases
Hospital Brighton.

RUPTURE OF THE EXTENSOR LONGUS POLLICIS TENDON.

I was much interested in paragraph 135 of the *Epitome of Current Medical Literature* (February 11th) on "spontaneous" rupture of the extensor longus pollicis tendon after Colles' fracture, as recently I had a case of this obscure complication.

Mrs. B—, aged about 55, a farmer's wife, sustained an injury to her right wrist by a fall at the beginning of December, 1921. Thinking it was merely a "sprain," she paid little attention to it at the time, and, in fact, proceeded with a big baking. It was not until nearly a fortnight later that she consulted me about the persistent pain, swelling, and

* From a Non-professional Medical Unit, St. Bartholomew's Hospital.
D

stiffness of the wrist. The evidence of an impacted Colles's fracture was undoubted, and the joint was immobilized by a single anterior splint for a week and then placed in a sling, gentle massago being kept up from the first. A week after removal of the splint, when very slight active movements had been commenced, quite suddenly one morning she felt the thumb weak and found that, although she could bend it into the palm, she could not straighten it. There was no pain whatsoever, and she was quite definite about the sudden onset of the disablement.

Separation of the long extensor was diagnosed and treated by splinting the thumb in the position of extreme extension. I have not seen the patient recently, but a fortnight ago recovery was not yet complete.

Owing to the apparent rarity of this complication—as evinced by Stapelmohr's inability to collect more than ten cases, including his own two—I think it worth while to place this on record.

S. NORMAN DYKES, M.B., Ch.B. Glasg.

East Kilbride.

INTESTINAL DISINFECTION IN ENTERIC FEVER.

In five cases of enteric fever I have used pulverettes of dimol (dimethylomethoxyphenol), which has been recommended as a non-poisonous preparation for intestinal affections. It is also stated to be non-irritant.

In the recommended doses of 2 to 4 grains in two cases intestinal haemorrhage ensued within forty-eight hours. The haemorrhage in each case was brisk, but quickly ceased on discontinuing the drug.

In three other cases, where the dose was reduced to 1 grain, then to 1/2 grain twice daily, nothing untoward occurred.

The cases were comparatively mild, and were selected for trial out of a total of 116 enteric cases admitted to our hospitals in 1921. The temperature in each case had come down to normal for a day or two, but was irregular and varied between 98° and 100° F. at the time of administration.

The number of cases is rather small to condemn the use of the drug in enteric fever, but the pungent taste of the pulverette when the outer coating is removed suggests that it might not be as free from irritation as the advertisement states.

CLINICAL AND SCIENTIFIC PROCEEDINGS.

ULSTER BRANCH.

At the winter meeting of the Ulster Branch, held in the Medical Institute, Belfast, on February 9th, the President, Dr. ROBERT REID, in the chair, the following cases were shown: Mr. FULLERTON, a young man with a brachial cyst, a young woman with a cystic hygroma of the neck, and a young woman with enlarged glands of the neck suggestive of Hodgkin's disease. With regard to the second case, Mr. CRYMBLE said he had attempted to remove a cystic hygroma of the neck, but it had returned with increasing rapidity of growth. Mr. FULLERTON also showed a tooth-plate which he had successfully removed by oesophagotomy; an attempt to remove it by the oesophagoscope had failed; it was opposite the arch of the aorta. He sutured the oesophagus in two layers.

Mr. CRYMBLE showed a case of a young girl with ankylosis of the left temporo-mandibular joint cured by excision of the head of the mandible; there had been a history of ankylosis for five years following some prolonged illness; the jaw opened to the extent of about 3 mm.; he had tried wedges, and secured a gain of only 2 to 3 mm. It was considered inadvisable to give a general anaesthetic, so, under a local anaesthetic with a short period of general anaesthesia, he removed the head and adjacent portion of the ascending ramus, and the jaw fell open after the five years' fixation; the right joint was free; six months after there was 30 mm. movement. He also showed a case of a young child from the left half of whose forehead he had removed a large black hairy mole in its entirety; union had been obtained without grafting, and no recurrence had taken place.

Mr. FULLERTON gave a brief account of the recent advances of cystoscopy and pyelography; he traced the development of the diagnosis of urinary affections from the days of guesswork to the present days of accurate knowledge gained by the newer methods and apparatus. The first substance used was collargol, but it was viscid and colloidal; its chief danger lay in its tendency to permeate the kidney if a greater force was used than 30 mm. of mercury. Recently solution of thorium nitrate was much used in America and was of great value. Solution of sodium bromide was now commonly employed; it was cheap, easy of manipulation, was innocuous and gave a good shadow. His own practice was to let flow from a Record syringe some of the solution into the ureteral catheter; he raised the syringe about two feet above the level of the patient; this was done in the x-ray room; the capacity of the normal kidney pelvis was about 4 to 12 c.cm.; the slightest loin pain showed tension of the pelvis, and was an indication for immediate stopping. Mr. Fullerton then showed a series of lantern slides of (1) pyelograms illustrating various abnormalities of the pelvis and ureter; in this way early cases of hydronephrosis, tumour of the kidney, tuberculosis, inflammatory conditions, could be recognized; (2) radiograms illustrating the value of the opaque catheter in determining (a) whether shadows seen on the plate were in relation to the kidney or ureter, or were outside this area; stereoscopy was very important in determining whether the shadows were in the same plane as the ureteral catheter; (b) the relation of foreign bodies, supposed to be in the neighbourhood of the kidney or ureter, to the opaque catheter. In this way accurate localization of the foreign bodies could be made, which was a factor of great importance when their removal was contemplated; the removal of missiles of war was much facilitated.

In speaking to the paper Professor SINCLAIR expressed his appreciation of it and of the slides, and Mr. IRWIN showed a slide where pyelography pointed to incipient hydronephrosis, which was cured by fixing the kidney.

Dr. MORROW read short notes of a case of a female, aged 40, who had suffered from "indigestion" since childhood: there was much flatulence, constipation, and some tenderness over the appendix. The symptoms did not fit into any of the recognized forms of abdominal trouble, and he had asked Mr. Irwin to do an exploratory laparotomy.

Mr. IRWIN said that duodenal ileus might be either acute or chronic. The acute embraced cases of acute dilatation of the stomach; the chronic was first described by Wilkie, and was now recognized as one of the causes of "indigestion" with recurring bilious attacks. The modern tendency was to explain diseases of the alimentary system on mechanical principles—for example, pyloric and ileo-caecal obstructions, etc. To this group Wilkie had added duodenal ileus: the cause of the obstruction was either in the root of the mesentery or in a prolapsing caecum and proximal colon. There was a frequent association with chronic ulcer of either stomach or duodenum, and it might occur with gall stones and pancreatitis. It occurred mostly in the female sex and the symptoms included: (1) a long history of indigestion; (2) pain and flatulence unless modified by careful dieting; and (3) periodic attacks of bilious vomiting. The attacks were made worse by prolonged standing, by constipation, and were frequently accompanied by a slight degree of jaundice. Similar symptoms were occasionally a sequel to gastro-enterostomy, where some obstruction occurred at the duodeno-jejunal junction, requiring Roux's operation in "Y." Signs were often absent, but occasionally epigastric fullness was made out. X rays had not given much help in the diagnosis. The treatment consisted in doing a lateral anastomosis between the jejunum and the duodenum, proximal to the root of the mesentery. The history, symptoms, and signs in Dr. Morrow's case agreed with those already given, and this mode of treatment was adopted with success.

Mr. IRWIN also showed an x-ray lantern slide illustrating obstruction of the duodenum in an old case of gastro-enterostomy, in which the symptoms agreed with those in Wilkie's cases, and in which the "Y" operation gave instant relief.

Mr. CRYMBLE read notes of a case of jaundice produced by enlargement of the head of the pancreas and relieved by cholecystoduodenostomy; the Wassermann reaction was positive, and it was considered probable that the enlargement was due to a gumma of the head of the pancreas. The patient is at present receiving antisyphilitic treatment and has put on a stone in weight. Mr. Crymble also read notes of a case of chronic obstructive jaundice due to enlargement

of the head of the pancreas. The symptoms were relieved by cholecyst-duodenostomy; the cause of the enlargement was not known.

Dr. CALWELL made some remarks on some of a series of nerve cases that he had demonstrated that morning in his wards in the Royal Victoria Hospital. The two chief points were the incidence of the toxin of encephalitis lethargica on the motor nuclei of the base of the brain, and evidence towards an explanation of the variety of the signs in myelitis.

Reports of Societies.

PSYCHOLOGICAL ANALYSIS IN DIAGNOSIS.

At a meeting of the Medico-Psychological Association of Great Britain and Ireland, held in the rooms of the Medical Society of London on February 23rd, with the President, Dr. C. HUBERT BOND, in the chair, Dr. T. S. GOOD (Ashurst Hospital, Oxford) read a paper on the use of analysis in diagnosis. Analysis, he said, must be used by every practising physician and surgeon in all kinds of cases; they must be influenced in their decision by what they saw, felt, and heard. Until a quite recent date the material upon which the doctor drew had been the conscious only; but, thanks to the ingenuity, the genius, and the patient work of Freud, a new source of medical knowledge had been opened to the profession, for he found that the solution of many of the problems as to the cause of neuroses and psychoses lay deeply buried in the unconscious mind of the patient. By special methods of technique these elements could be disclosed and brought into consciousness, and energy hitherto dammed back could be released to bring about improvement or cure. This had never been better demonstrated than during and after the war in cases of shell shock and neurasthenia; for many cases had been cured by psychotherapy, of which psycho-analysis was one of the instruments. By following the method of free association, physical conditions could be diagnosed which would otherwise escape notice or be only partially understood, because the key to the solution of the physical mischief lay repressed in the unconscious, and so could not be furnished by the patient in response to the usual examination.

Dr. Good elaborated the point by quoting in detail two cases, which had been diagnosed respectively as neurasthenia and hysteria.

The first case was that of a man, aged 50, who, after four years of war, was invalided out in 1918, with the diagnosis of neurasthenia. He had been under a varied treatment, and had tried, but with only partial success, to resume his pre-war occupation of motor-body making. There was nothing abnormal in the family history. At his first attendance at the clinic he was obviously apathetic and depressed, questions being answered slowly and with apparent indifference. He complained of a headache, great depression, inability to work, loss of memory, and was puzzled as to what could be the matter with him. He said that at times he felt "lost and giddy." The right side of his face did not move so well as the left. The tongue was protruded straight; the pupils were normal and equal in their reactions; fundi and vision were also normal. The only abnormality in the reflexes was that the plantar on the right was indefinite. Oppenheim's reflex was absent. Sensation, co-ordination, muscular sense were normal, also muscle tone, and there appeared to be nothing wrong with the organs; the pulse rate was 80.

The two abnormalities mentioned indicated that the case was not purely functional, but they did not form a sufficient basis for a firm diagnosis. He was unable to remember a certain period of his war experiences; he showed a disinclination to talk of the war, beyond stating that to it he attributed all his disability; he had a desire to be quietly by himself. After the third interview the man's demeanour changed, and he began to co-operate in his treatment, and to associate, with the result that his thoughts and feelings on his illness became clearer. A part of his life which he could not account for, however, was a period during a voyage at sea. He was on a ship when it was torpedoed at sea, but he could remember nothing between that explosion and his being in hospital. But details emerged in his mind as he evinced more interest and showed co-operation, and eventually he was able to describe what happened after the ship was struck. It appeared that he was thrown across the cabin, and his head came into violent contact with the bulkhead, injuring his left parietal region; he remembered feeling and hearing his skull crack. Feeling very sick and ill, he rushed, with others, on to the deck. He was rescued from the sea and taken to hospital. The whole of this amnesia was removed at one sitting, and the patient then expressed great surprise,

remarking, "I do not know why it is, but I feel all right, and am glad I can now remember everything." On returning to the clinic a fortnight later, he said his memory was good and he felt better, but instead of the dull headache he now had a new and more acute pain in the head, such as he had never experienced before, except when his head struck the ship's bulkhead, and the site was the same. This directed attention to a probable injury of the left parietal region, perhaps a fracture, with some resultant injury of the brain. A surgeon thereupon operated, and discovered a 2-in. fracture at the exact site of the pain and some bruising of brain substance. Previously there had been no suspicion of an organic element in the case. In this case, the amnesia having been cured, the clue was supplied by the patient himself. His attention to that stage had been so concentrated on his mental feelings that physical sensations were unnoticed until the mental conflict had been solved. The man had now recovered his mental poise, but the pain in the head was still present, and following the operation he had slight hemiplegia.

The second case was that of a man, aged 25, reputed normal before the war. After serving two years in the army he was discharged, the diagnosis being "hysterical fits." When his mother brought him to the clinic she said his disposition had now completely altered, for at times he was violent, aggressive, and irritable. He was said to have been having two kinds of fits, but both were ushered in by twitching on the right side of the face. Sometimes he became rigid, and seemed dazed and dull afterwards, with headache. In the other kind of fits he threw himself about, and was afterwards violent and irritable. The man was unable to remember any of the fits. When pressed to talk about the war he became irritable. Generally the reflexes on the right side were greater than on the left; on the right, also, there was some muscular weakness. At the second interview he was induced to talk about the war, when it was found that his memory of events for long periods was very defective; he did not remember why he had been sent home, nor when the fits started.

The detailed history which Dr. Good read showed that his trouble was connected with heavy trench-mortar warfare, in which he received a severe head injury. By the method of association the blank interval was made good, and then the patient talked freely about the episodes he experienced. After the recovery of the memory the emotional fits ceased, but the rigid fits increased in frequency. The right-sided weakness seemed to indicate that on that side there was increased intracranial pressure, probably due to head injury. Later the operation of decompression was performed, and since then he had had only two epileptiform attacks. He was discharged three months later. Four weeks afterwards his mother brought him again and said there had been no attacks since he was discharged, and that he was now working as a gardener.

After pointing out the parallelism in the two cases Dr. Good commented on the fact that one of them reacted by being depressed (introverted), the other by becoming excited (extroverted). The cases showed that psycho-analysis could be of use in diagnosing organic conditions.

The PRESIDENT, in thanking Dr. Good for his interesting contribution, deprecated any tendency to regard the materialistic and the psychiatric schools or lines of thought as being opposed to each other. The cases described in the paper showed how useful was the broad, inclusive view in unravelling difficult cases.

A short discussion followed, and in his reply Dr. Good elaborated at greater length some of the aspects of this line of inquiry.

GYNAECOLOGICAL SEQUELAE OF GENITAL TUBERCULOSIS OF CHILDHOOD.

At a meeting of the North of England Obstetrical and Gynaecological Society, held at Sheffield on February 17th, with the President, Mr. HAROLD CLIFFORD (Manchester), in the chair, Mr. MILES PHILLIPS (Sheffield) read a paper on the gynaecological sequelae of genital tuberculosis of childhood. He had been interested in these cases for several years, and his chief object had been to collect evidence to prove that certain gynaecological complaints—for example, primary amenorrhoea, dysmenorrhoea, dyspareunia, and sterility—might occasionally be due to damage done to the genital organs by tuberculous disease occurring during childhood and before organs were fully developed. The evidence of the original disease nearly always indicated tuberculous peritonitis, and for this he had usually to rely on statements made by the patient or a near relative. For instance, one patient knew that at the age of 11 she was very wasted, had a swollen abdomen, and was sent into the country for months. Many of the patients were supposed to have had typhoid fever, and

he had actually had two cases of genital tuberculosis sent to him direct from isolation hospitals where they had been under treatment for this disease. None of his patients had symptoms of phthisis, but two or three had puckered scars on the neck suggestive of old suppurating tuberculous glands.

As regards the damage done to the genital organs, he had found the Fallopian tubes affected in all cases, the mucous membrane being hopelessly destroyed in some, in others the abdominal ostium closed and the lumen distended with pulsatious material.

In some cases the endometrium was affected, leading to more or less obliteration of the uterine cavity, and then primary amenorrhoea, haematometra, hydrometra, or even pyometra, might occur. The functional disturbances were as follows: Menstruation was generally late in starting, infrequent, and scanty, but in a few cases commenced at the average age and was free or even profuse. It was always painful. In some cases it was absent or the products were retained as a result of obstruction to the outflow. Sterility, with or without dyspareunia, was sometimes the chief symptom, and married life was very apt to aggravate the patient's troubles.

The speaker read notes of five cases bearing on the subject of the paper, and in conclusion stated that the prognosis as regards sterility was a gloomy one. It was advisable to warn the patient or a responsible relative that the uterus or appendages might have to be removed. Conservative treatment was unsatisfactory; radical measures gave excellent results.

Dr. DORRIS (Manchester) read notes of a case in which ectopic pregnancy had occurred twice within four and a half months. Mr. LEYLAND ROBINSON (Liverpool) showed a specimen of sarcoma of the cervix. The patient was a 4-para, aged 40 years, and complained of backache and an offensive discharge of eighteen months' duration. The growth produced a localized ulcer indistinguishable from carcinoma, and it was only after operation that histological examination revealed its true nature. The epithelial structures of the cervix were unaffected, but the stroma was typically sarcomatous.

Mr. W. GORON (Leeds) read notes of a case in which rupture of the uterus had occurred through the scar of a Caesarean section performed two years previously. The uterus had been sutured with two layers of catgut at the previous operation.

The patient was admitted to hospital at full term complaining of pain in the back and lower abdomen. She was well enough to walk to the hospital, but within four hours she presented the symptoms of an abdominal catastrophe and operation was decided on. The abdomen contained a quantity of blood-stained fluid and a haematoma was present under the retro-vesical peritoneum and in the left broad ligament. This was due to the uterine scar giving way at its lower end. The uterine wall was incised to one side of the rupture and a dead child extracted. The old scar was then excised and the uterine wall sutured with catgut. Recovery was uneventful.

INFLUENCE OF COMPLICATIONS OF PREGNANCY ON INFANT MORTALITY.

A MEETING of the London Association of the Medical Women's Federation was held on February 4th at the Elizabeth Garrett Anderson Hospital, with Dr. LOUISA MARTINDALE (the President) in the chair.

Professor LOUISA McILROY spoke on the subject of complications of pregnancy and their influence upon infant mortality. She began by pointing out how the spread of ante-natal clinic work opened up a possibility of dealing with such complications at an early stage, and increased the possibility of the use of general medical treatment, which should obviate many of these complications when due to toxæmia and similar conditions. She regretted the fact that as yet there was no system of training midwives in ante-natal work, and urged that facilities for obtaining laboratory reports of specimens should be made more easily available. She then discussed at some length two types of complications of pregnancy: (a) contracted pelvis, and (b) toxæmic conditions and their treatment. In dealing with the treatment of pelvic contraction stress was laid upon the necessity for ascertaining the relationship of the head to the pelvis rather than dependence upon actual measurement of the pelvis itself. Induction was seldom to be advocated before the

thirty-sixth week, owing to the unfavourable prospect of the child's future life or welfare if done earlier. Caesarean section was still an operation associated with danger to the mother, and should not be lightly undertaken. The future of obstetrics lay in the ante-natal supervision, and this means many of the diseases of pregnancy could be prevented, and also it would do away with much of the interference at the time of labour. The application of force was associated with risks to the child's future welfare, except in cases of flat pelvis where the head was retained in the cavity of the pelvis owing to defective expulsive forces. The toxæmias of pregnancy included abortions, premature delivery of foetus, and haemorrhages. Accidental haemorrhage allowed its origin in some cases to a condition of toxæmia. The early phenomena of pregnancy, such as vomiting, were not physiological conditions, but were due to the retention of toxins, and to the upsetting of the balance of the internal secretory organs, their adjustment being affected by the new introduced organism, which is also an internal secretory organ although of a temporary nature. More laboratory work was required to aid clinical diagnosis and prognosis in cases of toxæmia.

An animated discussion followed, in which Dr. FRANCIS HUXLEY, Miss ROLTON, Lady BARRETT, Miss BASDEN, Dr. BRISCOE, Dr. LOUISA MARTINDALE, and others took part.

HAEMATO-PORPHYRINURIA.

At a meeting of the Oxford Medical Society on February 10th with the President, Dr. E. MALLAM, in the chair, Sir A. F. GARROD gave an address on the subject of haemato-porphyrinuria. He began by describing a case shown in Birmingham before the Association of Physicians last year. This was a boy of 5, who suffered from a bullous eruption of the face and exposed parts, which was accentuated in summer, and had led to much scarring. Furthermore, his teeth were pinkish, and he always passed urine of a port-wine colour; a specimen of the urine was shown to the meeting. The case was one of congenital haemato-porphyrinuria, of which only ten or eleven other cases had been described. The lecturer had himself shown some years previously that a trace of haemato-porphyrin was present in normal urine, and that this was slightly increased in diseases of the liver. But apart from these congenital cases, haemato-porphyrin in obvious amount only occurred in cases of poisoning by sulphonal and similar drugs. He then briefly discussed the chemical constitution of the substance present in the two conditions and its relation to other similar bodies. All cases of haemato-porphyrinuria suffered from hydroa vacciniforme (æstivale) and animal experiments had shown that haemato-porphyrin had the effect of sensitizing living tissues to the action of light. A case was also described in which a pathologist had shown the same sensitizing effect upon himself as the result of a small injection of haemato-porphyrin. The probable explanation of the condition was that a link in the normal conversion of haemato-porphyrin into bilirubin was missing; and that, like most of the other inborn errors of metabolism, this characteristic was a very rare Mendelian recessive. It was interesting that while about two-thirds of the cases occurred in males, sulphonal haemato-porphyrinuria was much commoner in women.

In the discussion that followed, Dr. TURRELL drew attention to the importance which might result, from the point of view of electrotherapy, from the discovery of a substance which would sensitize the tissues to the action of light and heat waves.

The following were among the exhibits shown:

1. Dr. STOBIE: A child with congenital heart disease. Sir A. F. GARROD discussed the pathology of the condition and pointed to the difficulties of the ante-natal endocarditis, as well as the maldevelopment theories.
2. Dr. STOBIE: A case of aortic stenosis in a discharged soldier. This patient had a definite thrill over the aortic arch, and the systolic murmur in the same region was conducted into the vessels of the neck.
3. Dr. MALLAM: A case of pityriasis rosea. The diagnosis from secondary syphilis and the treatment were discussed.
4. Dr. W. T. COLLIER, junr.: Specimens illustrating two cases of embolism of the superior mesenteric artery. One had occurred in an oldish man with a fibrotic heart and a thrombus in the left ventricle, and the other in a younger man with subacute bacterial endocarditis. Both cases had been diagnosed as acute intestinal obstruction. Mr. DONNS-PARKER quoted a similar case due to thrombosis following syphilitic endarteritis.

SUTURE OF THE SCIATIC NERVE.

A MEETING of the Section of Surgery of the Royal Academy of Medicine in Ireland was held in the Royal College of Surgeons on February 3rd, with Sir WILLIAM I. DE C. WHEELER in the chair.

Mr. R. A. STONEY reported a case of division of the left sciatic nerve sutured by him four and a half months after a gunshot wound of the buttock received in 1917. The ends were separated by an interval of over one inch and the lower end carried forward into the muscles. Both ends were freed, freshened, and sutured with fine silk. Sensation had completely returned, even for light touch. There was still one inch of wasting of the thigh, and one and a quarter inches wasting of the calf. Movements of the knee were full and strong. Plantar flexion of the ankle and toes was strong, but there was no voluntary power of inversion, eversion, or dorsiflexion of the foot or toes, though the muscles of the anterior tibio-fibular and peroneal regions appeared well developed. The patient had given up wearing a drop-foot support for the last three years; he was able to walk several miles; occasionally he was troubled with blisters on the great toe, but this had been less marked recently. It was not till two years after operation that a slight contraction of the calf muscles could be felt on attempted movement of the ankle.

Mr. M. DOCKRELL had noticed that in many cases of foot-drop the tibialis anticus had been over-developed in comparison with the extensors of the toes, causing a tendency to inversion of the foot. Mr. A. CHANCE asked if this patient took special pains to keep his foot warm; warmth often prevented ulceration in these cases, as in infantile paralysis. Mr. McCULLAGH found that after sciatic suture recovery was often favourable at first; then the tendo Achillis shortened and might require tenotomy. Mr. STONEY, in reply, said that the patient had worn a splint for a long period after operation, but had then refused to continue its use. This accounted for the laxity of the extensor group. He thought that ulceration of the sole of the foot was due to chilblains, as there was good sensation in this area.

Sir W. I. DE C. WHEELER showed two cases with stiff metacarpophalangeal joints treated by Vercell's splint. In one case the man was still wearing the splint and extension tapes. In the second almost complete function was restored.

Mr. H. STOKES showed a case of myositis ossificans of the brachialis anticus. The patient had been wounded by a bomb splinter and afterwards lashed by a horse. Repeated attacks of inflammation occurred, leaving much scarring. A piece of bone, 2 in. by 3/4 in., was removed, but the x-ray photograph taken after the excision showed persistence of a dense shadow at the site of operation. Mr. W. PEARSON thought that the kick was responsible for the condition, as myositis ossificans was uncommon after gunshot wounds.

Mr. A. BLANEY showed a large spleen successfully removed from a case of haemolytic jaundice of the familial type. The fragility test was positive with saline at 0.6 per cent. dilution, and was unaltered by operation; there were notches in the anterior border of the spleen.

Mr. W. C. STEVENSON reported the results of a year's work with radium emanation, with a summary of 160 cases. Sir W. I. DE C. WHEELER, Dr. T. KIRKPATRICK, and Mr. W. PEARSON spoke of the excellent results obtained by Mr. Stevenson in cases they had sent him, and considered that he claimed too little for this mode of treatment. Dr. KIRKPATRICK instanced a case of chronic syphilitic enlargement of the tongue with induration, which was the cause of great pain. Complete excision was considered; antisyphilitic treatment gave no relief, but the radium treatment almost immediately relieved the pain. Sir W. I. DE C. WHEELER referred to the improvement in inoperable prostatic cases. Inoperable cancer of the rectum, too, sometimes became operable after radium treatment. Dr. M. HAYES spoke of the danger of producing telangiectasis in effecting depilation by means of radium.

Mr. W. PEARSON showed a case of a boy where necrosis of the proximal phalanx had left a flail thumb. A piece of rib was grafted between the metacarpal and the distal phalanx, resulting in a stiff but opposable thumb; the grip was good. Radiograms of the thumb were shown. Mr. McCULLAGH said that he had transplanted an index finger to replace a lost thumb. The patient had afterwards complained that though the thumb was movable, it was too weak to allow him to use it for heavy labour, and requested its removal. This operation should be reserved for cases carefully selected in regard to occupation.

DEMONSTRATION OF ARTIFICIAL LEGS.

At a meeting of the Edinburgh Medico-Chirurgical Society on March 1st, Sir ROBERT W. PHILLIP presiding, Mr. C. W. CATHEART, F.R.C.S., showed a number of maimed soldiers wearing artificial legs, demonstrating in each case the level of amputation, the artificial limb that had been fitted, and a walking test. Before the war artificial limbs had been stereotyped, and little progress was being made; but the war had stimulated improvement. On the whole the best artificial legs now made were those of the American Rowley firm. Previous experience had shown the difficulty of fitting an artificial appliance to a Chopart amputation, and though the latest model was a considerable improvement, this amputation was inferior to the Syme amputation. The former reputation of the Syme operation had been confirmed by the late war, and the new type of leg suitable for this amputation was lighter and less cumbersome than the old. Amputation a little higher than the Syme nearly always gave trouble; a patient was shown in whom re-amputation at a higher level was found necessary and had given a good result. Where, therefore, the Syme operation was not available, amputation a little below the middle of the leg should be performed. Amputation a little below the knee, leaving a short stump of tibia about four inches long, had been condemned by the War Office memorandum. But he disagreed, for this operation retained the attachments of the thigh muscles below the knee and so secured the muscular control of the knee-joint. Even if the leg stump were less than four inches in the bent position, it provided a good support, besides retaining the great benefit of muscular control. Disarticulation at the knee-joint had also been officially condemned; but, using a leather bucket in the artificial limb, he had had satisfactory results with it; and in his experience it was a better operation than the Gritti-Stokes, the stump of which bore the weight well only in a few cases. A better operation than either disarticulation at the knee-joint or the Gritti-Stokes operation was amputation of the thigh at the junction of the middle and lower thirds. Patients illustrating these various sites of operation were shown; also two of amputation at the hip-joint or immediately below. In these higher operations the Rowley device of a pulley and a cord passed over the shoulder was demonstrated; by this the man as he walked hitched his shoulder (an imperceptible movement) and so produced an artificial extension and control of the knee. He finally demonstrated the Beaufort artificial limb, introduced many years ago by Count Beaufort, but which had remained almost unknown and unused in this country until now. In walking with this the patient had no movement, either at knee or ankle, and yet a smooth progression was achieved by rolling over a curved sole. This artificial limb had the simplicity of genius; it was effective, it was much lighter, and it was very much cheaper than other artificial limbs.

Professor F. M. CARR, speaking of the pendulum of fashion in surgery, mentioned how the Syme amputation stood high in credit in America after the Civil War, had thereafter fallen into disrepute, but had after the recent war recovered its former position. He recalled Mr. Cathcart's early and unsuccessful advocacy of the Beaufort limb; he was glad that he had now been able to demonstrate its value. Sir DAVID WALLACE said that the late Professor Annandale was more concerned in getting a good stump than in saving an inch or two of length, and this was a sound principle. Another point of importance was to keep the stump in good condition by a provisional limb until the permanent limb could be fitted. He had admired the walking of these patients over a smooth floor; but how did they get on over a rough or a sloping surface? He quoted the case of a patient of his own who, possessing both the old-fashioned peg leg and an artificial limb, preferred the former as more generally effective. Mr. CATHEART, in reply, said he did not disapprove of the peg leg, but its disadvantages were that it sank in mud or soft ground, that it wore out more quickly, and also made it more difficult for a man to find and keep employment than the artificial limb.

Internal Strangulation of the Bowel.

Professor F. M. CARR presented an analysis of twenty-three cases of internal strangulation of the bowel caused by bands, adhesions, and kinks. The cases were consecutive and covered a period of twenty years; fifteen were male and eight female, and the average age was 40; there were eleven deaths. Dealing with the symptoms and their comparison with those of

strangulated hernia, he spoke of the difficulty of diagnosis. It was fatal to delay until diagnosis could be made accurate; and it was very important that the general practitioner should send these cases earlier to the surgeon for exploratory laparotomy. He had divided his cases into the following groups: Bands of fibrous cords allowing herniation and then strangulation of a loop of bowel (two cases); bands producing a solitary constriction (nine cases); multiple constrictions, generally by omental tags which often had become unloosed at the operation (three cases); a mixed group, adhesions alone, or adhesions combined with constricting bands (eight cases). In fifteen cases the site of obstruction was the ileo-caecal region. Treatment might be very simple, consisting merely in division or release of the constricting band; but in the cases of difficulty it was directed first to the constricted area, and next to the distended proximal bowel. Various procedures—invagination of a damaged patch by Lambert sutures, enterotomy, enterostomy, enterectomy with primary suture or Paul's tubes—were discussed. It was very difficult to give general rules, and each case must be dealt with on its merits. But when he was doubtful of the vitality of the constricted area, or of the peristaltic vigour of the proximal bowel, he advised enterectomy, first dividing the bowel between clamps and freeing the mesentery; next carrying this length of intestine over the flank and free of the peritoneum, and thoroughly emptying the proximal bowel; then dividing above and performing an end-to-end suture.

Sir HAROLD STILES said that the high mortality in these cases was not the fault of the surgeon, and could be reduced by the general practitioner sending the patients sooner to hospital. The results were better where the bowel did not require enterostomy but could be put back. In doubtful cases his method was to empty the proximal bowel by taking a long loop of intestine well out of the abdomen and over the flank, tilting the patient and doing enterotomy, thus avoiding soiling of the peritoneum. Mr. D. P. D. WILKIE said that experimental research showed that the toxic products in the distended bowel were not bacterial toxins, but proteoses and toxic products of digestion. The cases that died had distended floppy jejunal coils, showing the necessity of a thorough emptying of the small intestine from the duodenum downwards in every case, and reserving enterostomy for the late and severe cases.

TREATMENT OF HYPERTHYROIDISM.

A MEETING of the Liverpool Medical Institution was held conjointly with the Manchester Medical Society on March 2nd, the President, Dr. J. HILL ABRAM, in the chair.

Professor G. R. MURRAY of Manchester read a paper on the treatment of hyperthyroidism and exophthalmic goitre. He stated that the cases in which hyperthyroidism occurred might be divided into three groups: (1) Simple hyperthyroidism, (2) toxic adenoma with hyperthyroidism, (3) exophthalmic goitre. The determination of the basal metabolic rate was helpful in determining the severity of the malady and the progress of treatment. In simple hyperthyroidism surgical treatment was not required, as medical treatment sufficed. In toxic goitre partial thyroidectomy was required if the trachea was compressed or if the toxic symptoms were marked. In mild cases, or in those in which operation was contraindicated, the hyperthyroidism could only be treated by medical means. In exophthalmic goitre medical treatment should be tried for six months. This consisted of rest, suitable diet, medicinal treatment with the use of x rays or radium. The importance of diet had been shown by the work of Dr. Chalmers Watson, Colonel McCarrison, and Professor and Mrs. Mellanby, though we could not without further evidence assume that these experimental results could be immediately applied to the treatment of the malady in man. The chief difficulty arose in selecting those moderate and severe cases most suitable for surgical treatment. The advantages were: (1) The saving of time by the rapid reduction of the hyperthyroidism and the relief of symptoms; (2) the diminution of the risk of injury to the myocardium; (3) the complete and rapid recovery in some cases. The disadvantages were: (1) The risk to life; (2) the uncertainty of the ultimate result owing to the difficulty in determining the extent of operation suitable in each case; (3) the tendency to relapse a year or more after operation.

Mr. GARNETT WRIGHT of Manchester read a paper on the surgical treatment of gastro-jejunal ulcer. After a short

review of the theories concerning the causation of jejunal ulcer in which the persistence of the original cause of the ulceration was emphasized, he read a short account of seven cases which had come under his care. The methods of surgical treatment adopted were classified under the following heads: (1) Local excision of the ulcer; (2) undoing the gastro-enterostomy and the formation of a fresh anastomosis; (3) partial gastrectomy; (4) undoing the gastro-enterostomy and restoration of the normal channel if necessary by a plastic operation. Of these methods, the last was considered to hold out the best prospects of a permanent cure.

Dr. J. GRAY CLEGG of Manchester read a paper on visual fields in lesions of the nervous system. Of 20,000 private patients he had made a charted record of the fields of some 900 individuals—that is, about 4.5 per cent. of all patients. He confined his attention to those connected with affections of the nervous system. After showing slides illustrating the visual paths and centres, charts of the defects noted in papilloedema as such, those in primary optic atrophy and retrobulbar neuritis were exhibited. There were several diagrams of the results of trauma of the optic nerve, of which two showed entire loss of an altitudinal half of the field, one a central absolute, and another a paracentral absolute scotoma. Various effects of pituitary disease were described. He also produced hemianopic fields; those of right-sided loss were associated with mind blindness in one and word blindness in two. Quadrant anopsia was shown twice, once of an inferior and once of a superior type. He had also come across one case of hemichromatopsia and word blindness. Another remarkable field presented a small remaining central area of sight after a left hemianopsia in 1903 and a right hemianopsia in 1911. An interesting case was that of a patient with inferior altitudinal hemianopsia affecting both fields. One illustrated the changes in a case of tumour of the left auditory nerve. Lastly, the peculiarities of fields of vision in the psychoneuroses were exhibited.

Rebichus.

BLAND-SUTTON'S "TUMOURS."

THE first edition of Sir JOHN BLAND-SUTTON'S *Tumours, Innocent and Malignant*,¹ appeared as long ago as 1893. The seventh edition, which has just been issued, retains the fascinating interest and personal touch of the first. Another attractive feature that has always characterized this work is the broad outlook, the product of the author's early studies on comparative pathology. One of the difficulties attendant on keeping a popular book up to date—and this, it need hardly be said, has been efficiently done—is to prevent the size from becoming unwieldy. The new volume contains sixteen pages more than the previous edition and the same number of figures, but twenty of these illustrations have been changed, so that, in spite of alterations necessitated by recent research, the size and general character of the volume remain much as before.

A noticeable change, however, is the omission of the chapter on endotheliomas, the contents of which, such as the mixed tumours of the salivary glands and psammomas, are dealt with elsewhere; the latter appear under the heading of epithelial tumours of the meninges, in a chapter which occupies the position in the book previously given to the consideration of endotheliomas. Sir John Bland-Sutton, as our readers know from the lecture published in February, considers psammoma to be a compact cluster of arachnoid villi infiltrated with cholesterol, and, like a calcified fibroma of the uterus, a dead tumour, though it generally wrecks the life of the patient by damaging the brain or spinal cord. The author thus appears to share the view of Dr. G. W. Nicholson—among others, it was the opinion, very vigorously expressed, of Professor Sharpey, the "father of British physiology"—that the term endothelioma should be consigned to oblivion, and it is perhaps for this reason that the question is not discussed, though the terms perithelioma and endothelioma are just mentioned in connexion with some growths of the breast and of the choroid coat of the eye respectively.

¹ *Tumours, Innocent and Malignant*. By Sir John Bland-Sutton, LL.D., F.R.C.S. London, New York, Toronto, and Melbourne: Cassell and Co. 1922. (Demy 8vo, pp. 805; 383 figures. 30s. net.)

INFECTIVE DISEASES.

Of the thirty-two volumes of the *Traité de Pathologie Médicale et de Thérapeutique appliquée*, edited by ÉMILE SERGENT, RIMBAUD-DUMAS, and BABONNEIX, the fourteenth to appear is that on *Infections à germe connu*,² containing sixteen articles by Professor Hutinel and seventeen collaborators. Other volumes of this series on parasitic and on unknown infections, on tuberculosis and on syphilis have already been published. The present instalment contains articles on a few tropical diseases, such as yaws, plague, and cholera, but it would seem more convenient for the reader to have had all these diseases collected together into one or more volumes.

In an introductory article Hutinel and Darré give a general sketch of the problems of infection, such as immunity, the clinical manifestations, which are divided into the general, local, and visceral symptoms, and specific treatment. The typhoid infections are considered in forty-seven pages by Lenglet, Ayrignac, and Brulé, with a note on psittacosis and the salmonellosis; the group of infections included under the salmonellosis, after Salmon, who, in 1886, described the first of them, includes paratyphoid B, Danysz's virus, the septicaemia of calves, and others. Philibert is responsible for the articles on septicaemias of various kinds, including meningococcaemia, and on facial erysipelas; Foehier's fixation abscess, induced by the subcutaneous injection of 2 c.cm. of turpentine, has given good results in septicaemia, but in some instances suppuration does not follow this injection and then the outlook is particularly dark; the intravenous injection of specific serums and vaccines is firmly discountenanced. In the section on cerebro-spinal fever (Baur of the Val-de-Grâce) special attention is directed to the untoward effects of intrathecal injection of serum—namely, seric meningitis—in which the cerebro-spinal fluid, though containing pus cells, is free from meningococci, and anaphylactic manifestations, which fortunately are rare and should with care not occur. Lemierre gives a comprehensive sketch of tetanus, and naturally refers to its occurrence in the great war. Writing on Malta fever, H. Roger of Marseilles says that, as the British Government protested against this name for a disease that is far from being confined to that island, the Académie de Médecine of Paris has proposed the names melitosis, or preferably melitococcaemia. As regards the specific treatment, vaccines are recommended for the afebrile periods of the subfebrile forms and serums for cases with high fever and acute paroxysms.

In a copiously illustrated article on leprosy Amcuille describes and figures the early evidence, pointed out radiologically by Colombier, of bony atrophy of the terminal phalanges of the toes; he speaks with wise reserve of the therapeutic value of Doyle's uastine or the ethereal extract of the non-pathogenic *Streptothrix leproides* cultivated from a leproma. The volume concludes with accounts of some tropical diseases, such as Oroya fever and verruga. In the well-illustrated article on yaws, the condition of gonodon, originally described in 1882 by the late Professor A. Macfister as "the horned men" of Africa, is included, as urged by Chalmers and by Nell, among the tertiary lesions.

The volume can be confidently recommended as a clearly written and up-to-date summary of the infections of known origin.

WORMS AND APPENDICITIS.

Dr. REINDORF's monograph³ presents an account of his observations, made during the past ten years, of several hundreds of cases of appendicitis, in which the appendix contained oxyuris. His material is derived chiefly from civilian hospital practice, but also from the German army during the war. It contains evidence of much painstaking research, and of careful and original thought. The reader gains the impression that while Dr. Reindorf is possibly influenced by eulhasiasm as well as facts in his general conclusions, his subject probably deserves more attention than it has received.

The first section deals chiefly with the literature relating to the occurrence of intestinal worms in the appendix. It is interesting, and apparently very complete.

In the second section the histo-pathology of primary ulcers

caused by the oxyuris is accurately described, and the assertions in the text are well borne out by excellent microphotographs of his preparations. He shows that where the parasite lies in contact with the epithelium of the mucous membrane of the appendix an ulcer develops. This he attributes chiefly to toxins produced by the worm, and partly to its mechanical pressure and boring action. The occurrence of ulceration is dependent on a serological reaction, of anaphylactic nature, between host and parasite. These defects are quite typical, and can be attributed with certainty to oxyuris, even when the parasite is not present at the time of examination. The worm may penetrate deeply into the lymphatic tissue, and even through the muscular and serous coats, though the latter occurrence is extremely rare. These "oxyureduledefekte" have been regarded by some as artefacts. Dr. Reindorf proves they exist during life, chiefly on the evidence of epithelial regeneration. The trichocephalus also bores into the mucous membrane of the appendix. The ascaris fills up the appendicular lumen and produces extensive epithelial lesions, presumably by toxic action, but its presence in the appendix is extremely rare.

The third section is devoted to the clinical aspect of the subject. Pain, in its mode of onset, character, duration, and sites, presents no features distinguishing it from that produced by the commonly recognized types of appendicitis. It is considered to be due to the action of the oxyuris toxin on the vagus and sympathetic nerve endings in the appendicular wall; it may be very severe with a minimum of anatomical disturbance. If the appendix alone is infected, appendicectomy causes the pain to disappear; but if the colon is also infected it may persist. The temperature in these cases exhibits no characteristic features; it is extremely variable in relation to the severity of the lesion, as in all types of appendicitis. The presence of worms in the appendix does not always cause symptoms (13 per cent.), and the symptomless oxyuris carrier is compared to the carrier of potentially pathogenic organisms. Dr. Reindorf believes that the individual susceptibility in both cases, and the varying susceptibility of an individual from time to time, are referable to serological conditions. The differential diagnosis is discussed briefly, but it is suggested that most "obscure" abdominal conditions—for example, mobile kidney, mobile caecum, hysterical pains, etc.—are to be traced to oxyuris infection. Gross infection constitutes only 4 per cent. of all cases. In the remaining 96 per cent. there are only a few worms—often only one. The male is practically invisible when embedded in mucus. To these conditions the author attributes the almost universal failure to observe the parasite except in the rare cases of gross infection. This section includes tables of cases, setting forth the main points, as well as detailed histories.

In the fourth section the pathogenesis of appendicitis is discussed. All appendicitis, with the exception of the superficial catarrhal form, is, the author thinks, due to primary ulceration, followed by secondary bacterial infection. The oxyuris is considered to be by far the commonest cause of primary ulceration, while trichocephalus is variable and ascaris very uncommon. Primary ulceration may be due to tuberculosis, typhoid fever or dysentery, concretions, foreign bodies, or rare parasites such as *Distomum haematobium*, but all these are uncommon as compared with oxyuris. The occurrence of primary infection without antecedent ulceration is emphatically denied.

Two types of oxyuris appendicitis are recognized: (a) The superficial catarrhal form, due to the toxic products of the worm alone, causes desquamation of the epithelium, transudation of serum, leucocytic infiltration, and toxic haemorrhages in the submucous tissue; (b) secondary bacterial infection of ulcers caused by the worm may lead to consequences varying between chronic fibrosis and perforation, with general peritonitis. In many cases which recover spontaneously such conditions as kinks, adhesions, and stenosis result, and lead to further inflammatory developments later; but Dr. Reindorf insists that in almost all these cases oxyuris infestation is the ultimate cause. In 50 to 60 per cent. of his cases operated on for appendicitis in children the appendix contained oxyuris, in adults 25 to 30 per cent., while in a much higher percentage evidence of worm ulcers and remains, such as portions of cuticle or parasite's eggs, showed the true causal factor. Dr. Reindorf thinks the worms often leave the appendix on account of inflammatory changes and raised local temperature. An excellent account is given of the morbid anatomy of the infected appendix. A rare case of actual perforation by the parasite is cited. The spread of infection from the primary ulcer by the lymph stream is

¹ *Traité de Pathologie Médicale et de Thérapeutique appliquée*. Publié sous la direction de Émile Sergent, L. Rimbaud-Dumas et L. Babonneix. Tome XVI: *Infections à germe connu*. By various writers. Paris: A. Maloine et Fils, 1921. (Demy 8vo, pp. 65; 104 figures. Fr. 29.)

² Die Wurmsinfestationen. Von Dr. A. Reindorf. Berlin: S. Karger, 1920. (Roy. 8vo, pp. 214; 52 figures.)

discussed, as is the occurrence of intramural abscess. The infective agent may not be arrested before the meso-appendix is reached, and the unexpected onset of post-operative peritonitis or wound infection, where an apparently normal appendix has been removed, is explained by the division of infected lymphatics. Appendicitis due to foreign bodies is estimated at 1 to 2 per cent. The appendix normally fills along with the caecum and is quite capable of emptying itself, but such bodies as fish-bones, bristles, or enamel splinters may stick and cause ulceration and secondary infection. Dr. Reindorf believes that a concretion never causes pain. Very rarely it may cause direct pressure ulceration, or indirect ulceration by obstruction, followed by retention of secretion and empyema. The very common association of oxyuris with concretions (50 per cent.) suggests that there is an etiological relationship—the fibrosis induced by a chronic worm infection favouring the development of a concretion.

In the fifth section percentage figures are given of the incidence of oxyuris, trichocephalus, and ascaris, derived from post-mortem examination of soldiers of the European nations engaged during the war. Statistics are quoted also from the literature of those who had not the opportunity to examine. Oxyuris was present in 9 to 25 per cent. of all cases. Of all infected cases the parasite was found in the appendix in 59 per cent. Trichocephalus infection was more common, but its presence in the appendix relatively less frequent. Ascaris infection was common, but it was not observed in the appendix. On the ground of the high percentage of oxyuris infection among soldiers, Dr. Reindorf prophesies a considerable post-war increase in appendicitis.

In the sixth section some suggestions as to the prophylaxis of appendicitis will be found. More research is required as to the action of anthelmintics, and as to whether they reach worms in the appendix. The extreme difficulty of clinical diagnosis is discussed. An active campaign against the oxyuris is recommended, and it is thought that a great advance would be effected if the importance of the question were generally recognized by the profession. Much could be done by the medical school inspector, and pamphlets dealing with the subject might be circulated among parents of school children. It is emphatically stated that in the presence of symptoms of appendicitis, even of a mild degree, anthelmintic treatment is unjustifiable, and early operation is strongly advocated.

It is unfortunate that this excellent material has not been presented in a more accessible form. The sequence of thought in the book is bad—one might almost say it is not arranged. There is excessive and quite unnecessary repetition. One regrets that so much space is devoted to the discussion of priority of publications, and to the detailed histories of various debates in which the author has been engaged during the past ten years. A scientific monograph is not a fit place in which to air his personal grievances against his opponents; and his criticism of their opinions often assumes an unpleasantly personal character. The book is interesting and suggestive, but it will tax the reader's patience considerably.

GRAVES'S DISEASE.

DR. CASSIO DE REZENDE has published in a small volume an interesting little essay on the etiology and treatment of Graves's disease,⁴ which he presented to the National Academy of Medicine of Brazil in support of his claim to be elected a corresponding member. He first discusses the various theories which have been proposed to explain the pathogenesis of the disease, such as bulbar neurosis, hyperthyroidism, stimulation of the sympathetic system, pluriglandular disturbance, and intestinal intoxication; he dismisses all of them as unsatisfactory, and advances the hypothesis that it is an infection. This theory, he thinks, explains almost if not all the symptoms, and reconciles certain apparently contradictory facts. Graves's disease he describes as a chronic morbid process, presenting intervals of quiescence which are not infrequently complete, alternating with periods of acute exacerbation. How, he asks, is this fact to be explained except on the supposition of an internal parasite which, in the course of its evolution, also presents phases of attenuation and increased virulence? The occurrence in Graves's disease of ophthalmoplegia similar to that met with in syphilis, diph-

theria, influenza, and lethargic encephalitis, and the occasional presence of fever like that observed in syphilis, are further manifestations of infection. Moreover, the numerous lesions of different kinds found in the various organs after death and the changes in the blood are, he thinks, precisely those met with in infectious processes. The successful action of two drugs, arsenic and quinine, whose only point of resemblance is their parasitocidal action, is used as a further argument in favour of the infective origin of Graves's disease. The author concludes by advocating the use of antimony salts in the form of tartar emetic intravenously, as they have been found of even more value than arsenic in the treatment of protozoan infection. Dr. de Rezende shows a remarkable familiarity with modern English medicine, which is as gratifying as it is rare in foreign writers.

TREATMENT OF FRACTURES.

For the new edition of Mr. E. W. HEY GROVES'S book, *On Modern Methods of Treating Fractures*,⁵ the text has to a great extent been rewritten. The bulk of the book has thereby been greatly increased, but its value has also been increased. Since 1916, when the first edition appeared, experience of the treatment of fractures, more especially of the various complicated injuries following gunshot wounds, has grown greatly. In the first edition perhaps undue prominence was given to the various forms of open operation, to the exclusion of the more generally applicable methods of extension and splinting. In the present volume no claim is made for any one system, but it is clearly shown that the various methods of treatment should be used as occasion requires. Perhaps the most interesting section of the book is that which embodies the author's Jacksonian essay on bone-grafting. It gives a digest of the work of the various pioneers, and describes much original work carried out by the author himself. The increase in the size of the book is in part due to the introduction of detailed accounts of the treatment of the fractures of the upper and lower limbs. It should perhaps be pointed out that no systematic account is given of the various fractures themselves and their displacements; this knowledge, it is presupposed, has already been gained from clinical experience or from one of the various textbooks on surgery. It is satisfactory to find that the author condemns the almost criminal practice of plating a septic compound fracture.

Perhaps the outstanding fact to be learnt from the book is that in order to get good results in the operative treatment of fractures, either by plating, bone-grafting, or pegging, the operator must be a really skilled carpenter. It would almost seem necessary for the surgeon to spend at least a year in a workshop gaining skill as a cabinet maker! However this may be, it is right to lay emphasis on the point that complicated operations on fractures are not to be undertaken light-heartedly. Many of the procedures, which in the author's hands give excellent results, require such technical skill that they will probably never gain favour with the general surgeon. Possibly the day may come when the treatment of the more complicated fractures will be undertaken by a "fracture specialist."

The book is excellently illustrated with diagrams and reproductions of skiagrams. It should prove of great interest as a scientific and up-to-date treatise on the subject.

A POCKET SURGERY.

MR. D. C. L. FITZWILLIAMS'S new book⁶ is a frank attempt to confine the whole realm of examination surgery within a small compass. It is possible that his book may become famous, as did the "Breeches" and "Treacle" Bibles, from a remarkable statement. On p. 17 it is said that anthrax has lately "been imported from Japan very largely in the thistles of shaving brushes!"

The book has a good deal to recommend it, as it is more than an abstract of some well-known textbook. It bears the impress of a vigorous personality, and, brief though the descriptions necessarily are, the author succeeds in interesting his readers.

⁴ *On Modern Methods of Treating Fractures*. By E. W. Hey Groves, M.S., M.D., B.Sc. Lond., F.R.C.S. Eng. Sec. 2d edition. Bri. Med. J. Wright and Sons, Ltd. London: Simpkin, Marshall, Hamilton, Kent, and Co. Toronto: The Macmillan Company of Canada, Ltd. 1921. (Roy. 8vo, pp. xix + 435; 295 figures. 30s. net.)
⁵ *A Pocket Surgery*. By D. C. L. Fitzwilliams, C.M.G., M.D., Ch.M., F.R.C.S. Edin. London: Edward Arnold. 1921. (Cr. 8vo, pp. 318, 10s. 6d. net.)

⁶ *Lições reflexas sobre a etiopathogenia e o tratamento da molestia de Graves*. Memoria apresentada á Academia Nacional de Medicina pelo Dr. Cassio de Rezende. Guaratingueta, S. Paulo, Brazil. 1921. (Demy 8vo, pp. 40; 5 illustrations.)

All such manuals as this are apt to leave the reader a little breathless after his rapid chaso from cover to cover. Students, however, seem to like their cram books just like that, and we can assure them that Mr. Fitzwilliams will lead them on no false scents.

NOTES ON BOOKS.

THE new number of *Brain*? (Vol. xlv, Part IV) is larger than usual, containing, as it does, over 240 pages, without counting the title-page and index to the volume. It opens with a paper by Professor Harvey Cushing, of Harvard, on the field defects produced by temporal lobe lesions. It contains also a long paper by Dr. George Riddoch and Dr. E. Farquhar Buzzard on reflex movements and postural reactions in quadriplegia and hemiplegia, with especial reference to those of the upper limb; a paper by Dr. Ramsay Hunt, of New York, on primary atrophy of the dentate system (a contribution to the pathology and symptomatology of the cerebellum); and one by Dr. F. M. R. Walshe, of the Medical Unit, University College Hospital, on disorders of movement resulting from loss of postural tone, with special reference to cerebellar ataxy. The proceedings of the Section of Neurology of the Royal Society of Medicine are reported, and there are the usual notices of recent publications.

The eighth edition of Mr. J. F. BINNIE'S *Operative Surgery* differs only slightly from the seventh, which appeared five or six years ago; several additions have been made to the chapters on thoracic and plastic surgery. Perhaps the most noticeable feature of the book is the space devoted to the rarities and complications met with in operative practice. The volume is a mine of information; no operative measure ever made use of seems to have escaped the author's notice. The book is, perhaps, not quite suitable for the junior student, but it should often prove a valuable work of reference in those frequently occurring cases about which nothing can be discovered in the ordinary text-books.

We have received a number of fasciculi of a German work on diagnostic and therapeutic errors and their avoidance,⁹ in which the commoner mistakes made in surgery, medicine, gynaecology, and ophthalmology are recorded and discussed. No single section of the work appears to be complete; it seems to be written for the use of specialists rather than general practitioners of medicine. The full title of only a single fasciculus—that dealing with diseases of the spinal cord and peripheral nerves—is given in the footnote.

The book by Dr. BREGMAN of Warsaw on sleeplessness and its treatment¹⁰ gives a general account of the association of sleeplessness with disease, illustrated by cases quoted from his own practice. The last chapter of the volume gives an account of the many hypnotic drugs that may be used to promote sleep, together with the author's views as to their respective advantages and disadvantages, and contains much information of service to the practising physician.

A few articles by Mr. PIKE, which appeared in the *Practitioner*, have been gathered together to form a little book to which the author has given the novel and arresting title of *Permeating Mastoid Meningitis*.¹¹ There is nothing perhaps very original except the title, but if the writer succeeds in drawing the attention of practitioners to the most dangerous complication of disease of the middle ear he will doubtless have accomplished his aim. It is to be hoped, therefore, that the book will be widely read.

⁹ London: Macmillan and Co., Ltd.; New York: The Macmillan Co. 1921. (Price 6s net.)

¹⁰ *Manual of Operative Surgery*. By J. F. Binnie, A.M., C.M.Aberd., F.A.C.S., London: H. K. Lewis and Co., Ltd. 1921. Eighth edition, revised and enlarged. (Roy. 8vo, pp. xxiv + 1311; 162 figures. £3 8s. net.)

THE Istituto storico italiano dell' arte sanitaria was founded in 1920 to promote and organize the study of hygiene along historical lines, and to collect illustrative material in a museum and library. It has begun to issue a *Bollettino*, the first number of which opens with an article by Dr. Capparoni on Giovanni Battista da Vercelli, a nineteenth-century syphilologist. The general secretary of the institute is Dr. Pietro Capparoni, Via del Pozzetto 103, Roma 7.

MEDICINAL AND DIETETIC PREPARATIONS.

Pure Barium Sulphate.

WE have received from the British Drug Houses a specimen of barium sulphate as supplied by them for x-ray diagnosis, and have submitted the article to analysis, with results showing that it is a very pure product. By repeated exhaustion of the sample with water or dilute hydrochloric acid no solution of barium was obtained beyond the infinitesimal traces corresponding with the solubility of barium sulphate. It contained no impurity except a trace of alkali sulphate, and the proportion of this did not exceed 0.01 per cent. The protective action of alkali sulphate against dissolution of barium sulphate through the reactivity of the latter would be a valid reason for the sanction of a much more considerable percentage of alkali sulphate.

The material is neatly put up in a case of separate cardboard packages, each package containing four ounces of barium sulphate, the quantity usually required for a single meal; a leaflet gives directions for the preparation of the meal and memoranda on the average time of its passage to the different regions of the alimentary canal. The way in which the product is packed will make it very convenient for keeping a supply in reserve ready for use; barium sulphate stored in this form should prove a safeguard from the dangers of such accidents as have occurred from resort to ordinary commercial supplies.

New Season's Cod-Liver Oil.

Messrs. ALLEN and HANBURY have sent us a sample of the new season's cod-liver oil, recently received from their Lofoten factory. It is pale in colour, has little odour, and the fishy flavour is slight. They send us data showing that the acid value is low, and that the iodine absorption figure indicates a high content of unsaturated metabolized fat. They inform us also that the oil has been prepared with a minimum of exposure to conditions favouring oxidation, which, as is well known, are inimical to the preservation of the activity of the fat-soluble A vitamin. The preparation appears, therefore, to be one upon which the profession can rely.

RADIUM THERAPY.

II.

ANNUAL REPORT OF THE MANCHESTER RADIUM INSTITUTE.

A PREVIOUS article on radium therapy, dealing with the work of the London Radium Institute last year, appeared in our columns on March 4th (p. 355). The annual report of the Manchester and District Radium Institute for 1921 covers the work of a year which was regarded as a period of transition, and which has been an important one in the history of the Institute. In the original scheme, which came into effect at the beginning of 1915, there were eight participating hospitals, and their patients were received and treated at the Institute, which worked in premises within the Manchester Royal Infirmary. The work of the Institute steadily increased, and the accommodation at the infirmary was found to be inadequate. Throughout the period of its existence Sir William Milligan has acted as honorary secretary and treasurer of the Institute, and its success has owed much to his enthusiasm. Though the generosity of Sir Edward and Lady Holt, last year a building close to the Royal Infirmary was equipped and furnished as a hospital, and handed over to the committee of the Institute, which was transferred there. In this hospital have been provided thirteen beds, which are used solely for radium treatment, and there are also eight treatment rooms for patients receiving local applications, a well-equipped operation theatre and sterilizing room, research laboratories, a workshop, and other necessary accommodation. This complete hospital for radium treatment, as was noted in our columns at the time, was opened last October.

In his annual report of the Institute for 1921 the radiologist, Dr. Arthur Burrows, states that during the year 783 cases presented themselves, which shows a slight decrease from the previous year, due probably to the changes which have been mentioned. The physicist reports that 525 emanation plates and 1,231 emanation tubes were made during the year. Sixty cases of malignant disease, exclusive of rodent ulcer, were rendered free from signs and symptoms of disease during the year, including four cases of carcinoma of the uterus previously inoperable, which were rendered operable and the operation performed. As 564 malignant cases were treated, these 60 cases represent nearly 12 per cent. of the total number of cancerous patients seen, a proportion which is practically the same as in 1920. The

number of cases of rodent ulcer treated was 71, of which 36 were permanently cured; 24 non-malignant conditions were also cured. The total number of attendances of patients during the year increased from 5,424 in 1920 to 6,167, but this number does not include in-patient treatments.

Dr. Burrows includes in his report an analysis of 2,595 cases which were treated at the Institute between the years 1915 and 1919. This number excludes those who, although examined, did not present themselves for treatment and those who were so very advanced as to be hopeless even for palliative treatment. Of this total, 1,753 were suffering from cancer, 14 from papilloma of the bladder, and 14 from mediastinal tumour. In addition, 267 patients were suffering from rodent ulcer, and 575 cases suffered from various conditions which were usually described as non-malignant, although a considerable proportion of them would, if allowed to progress, have terminated in death. Dr. Burrows states that practically all the cancer cases, except those of cancer of the skin, were inoperable, with the exception of a very small number which were treated by radium for such special reasons as bad general health, failing heart, or diabetes. A certain number of cases of early carcinoma of the cervix of the uterus received prophylactic treatment immediately before operation. Under these conditions 135 of the patients are alive and well to-day, having lived from periods varying from two to seven years; this is equal to just over 7½ per cent. of the cancer cases treated, or 6½ per cent. omitting cases of skin carcinoma, although a number of these were inoperable. Dr. Burrows points out that about 50 per cent. of the symptomatic cures—which are not claimed as "cures," but are often examples of excellent palliation—annually reported eventually recur.

TREATMENT OF CARCINOMA.

In regard to the treatment of carcinoma of the breast, 16 of the cases treated have been well for over two years (2 of them for between six and seven years), and one inoperable case was eventually operated on. More than half of the cases of carcinoma of the breast treated by radium were recurrences after operation. Of the cases of carcinoma of the cervix of the uterus treated, 8 previously inoperable were, subsequent to treatment, operated upon, and 13 have been well for over two years (including 2 who have been well for between five and six years); in a number of cases after the operation the growth of the uterus was found to have completely disappeared. Twenty-five per cent. of the cases of carcinoma of the lip have remained well for over two years, 2 of them for between four and five years. Dr. Burrows considers that carcinoma of the mouth and tongue is not a favourable condition from the radium point of view, owing to the rapid formation of secondary deposits. The use, however, of unscreened emanation tubes has improved results; in 29 of the cases treated the primary growth was caused to disappear, and 7 cases have been alive and well for over two years (one of them for between six and seven years). In carcinoma of the rectum it is uncommon to get a really good result, and palliation is the most that can be hoped for; but one patient has been alive and well for between five and six years, and another more recent case has been treated with success up to the present. Thirty-three cases of carcinoma of the skin, or nearly 25 per cent. of the total treated, have been alive and well for between two and seven years. Carcinoma of the thyroid gland is considered to be a favourable condition for radium treatment, and 4 cases have been well for over three years, 2 of them for between six and seven years. Of the cases of carcinoma of the vulva 4 have been well for over two years, one of them for between five and six years. The burying of unscreened tubes is believed to be the most hopeful method of treatment in these cases at present, but the reaction is apt to be extremely prolonged and painful. All the cases treated have been very advanced ones, and in Dr. Burrows's opinion surgery is likely to be a less painful method of treatment in early cases, while perhaps diathermy may obviate the difficulty in the matter of pain. In abdominal carcinoma, if there is widespread dissemination of the growth little can be hoped for from radium treatment. In two cases of carcinoma of the colon promising results were obtained, one case remaining without a sign of growth for two years, but subsequently dying of a recurrence, while the other lived for three years in good health, eventually dying, according to the information received, of cerebral haemorrhage. Carcinoma of the stomach

will often diminish in size for a time if tubes are buried in the growth, but no completely successful result has so far been obtained in Manchester.

TREATMENT OF SARCOMA.

In lymphosarcomas the immediate results of radium treatment, says Dr. Burrows, are often brilliant, but usually the disease spreads elsewhere and eventually kills the patient; two of these cases have been alive and well for between three and four years. Of the cases of sarcoma of the nasopharynx two have been alive and well for between six and seven years, and one for between two and three years. Spindle-celled sarcomata react very sluggishly to radium, and prolonged, not too violent, treatment for a long period is necessary. In the end, however, they appear to repay the trouble taken, for the prospect of cure appears to be much greater than in the case of the small round-celled type, which locally, under radium treatment, seem to melt away and subsequently recur.

TREATMENT OF OTHER MALIGNANT CONDITIONS.

Of the cases of endothelioma of the parotid gland, ten have been alive and well for over two years, three of them for over five years. This represents over 30 per cent. of the cases treated, many of them recurrences following operation, and this percentage of cures is so high as to suggest that radium is likely to be the treatment of choice in the future, especially because of the good cosmetic results. Dr. Burrows considers that no surgeon could operate on a case of endothelioma of the parotid gland without the help of radium, either for prophylaxis or in case the operation cannot be completed without destroying the facial nerve.

Most of the cases of papilloma of the bladder were advanced cases, and four of those which were treated have been alive and well for over two years, one of them for between six and seven years.

Of the patients suffering from rodent ulcer, 125 have now been well, after treatment, for a period varying from two to seven years. A very large number of advanced hopeless cases have been treated, but still 50 per cent. of all cases have been cured, and if properly treated recurrence appears to be rare.

TREATMENT OF NON-MALIGNANT CONDITIONS.

Fifty-two cases of exophthalmic goitre are recorded as cured; that is to say, all symptoms and signs of disease have disappeared for over two years, and only one recurrence is recorded. Much patience is needed in the treatment of these cases, for the application of radium is a long process, and the treatment may last from two to three years. The cases of Hodgkin's disease may be divided into those under 25 years of age and those who are middle-aged; the former give excellent results, but the middle-aged cases seem almost hopeless, except for palliation. Perhaps, suggests Dr. Burrows, they may be two different diseases. Keloid and vicious scars nearly always yield to radium treatment, and sixteen such cases have been cured, although some mark must always remain. Radium is stated to cure almost all cases of "spring catarrh," and appears to be the most satisfactory treatment of this disease. Fifty per cent. of the cases of cavernous naevus were cured practically without any mark remaining, and capillary naevi, says Dr. Burrows, can always be made paler, but if treatment is kept on too long telangiectases appear. For excessive uterine haemorrhage radium is stated to be a specific. The Institute records only one failure in this condition, and that patient did not submit to a second application. If by using a small dose the risk of the necessity of a second application of radium is taken, with young women menstruation often returns to normal, and cases are recorded in which they have married and had children subsequently. A good proportion of lupus vulgaris cases, if not too advanced, can also, it is stated, be cured by radium, contrary to general expectation.

THE Calcutta Medical College students recently decided, as a protest against the present Government policy, to suspend duty in hospital and attendance in classes.

It is reported from Washington that Dr. Hubert Work, president of the American Medical Association, who at present holds the office of First Assistant Postmaster-General, is the probable successor as Postmaster-General of the United States to Mr. Will H. Hays, who is resigning to become the head of the cinematograph industry of the United States at a very large salary.

HOSPITAL POLICY.

III.

THE CONTRIBUTORY SCHEME IN OXFORD.

[DR. WILLIAM COLLIER, honorary consulting physician to the Radcliffe Infirmary and County Hospital, has been good enough to send the following account of the Oxford contributory scheme.]

In the SUPPLEMENT of February 25th appeared a report on the organization of voluntary hospitals, with reference in particular to the reception of paying patients, and the position at the hospital with which I am associated may be of interest in regard to this, although our hospital happens to be in a more fortunate position than most. During the past year the whole finances of the hospital were placed on a better basis by generous support from all classes of the public. The administration and organization of the whole scheme of financing have been revised and greater efficiency and economy in working were effected. The hospital is one of the few in the country that have had a balance in hand on the year, and it appears as though it will not have to ask for any grant from the regional court appointed under the terms of the Voluntary Hospitals Commission. In addition, it must be one of the few hospitals in the country that have taken on a great deal of new work during the year—a maternity home with a resident physician having been added, a new convalescent home equipped, and a preliminary training school for nurses opened. All this has been achieved by the aid of a new scheme of weekly contributions, covering the whole district within range of the hospital. In an area that is mainly agricultural, without large towns, but dotted with prosperous market towns and villages, over £17,000 was raised in the year in twopenny contributions; and in other ways, mainly from the working classes and by entertainments, a total of over £25,000 in new money was received, being an increase of about £20,000 on the previous year's income, the total income this year being just over £41,000.

The report of the council on voluntary hospitals states that in schemes for providing hospital benefit it is undesirable that the hospitals concerned should undertake any insurance risk, or, in other words, undertake to provide hospital benefit when required in return for a periodic payment by an individual or a group of individuals. It goes on to state that the acceptance by voluntary hospitals of insurance risk under any scheme for the provision of hospital benefits would prejudice the primary consideration in the admission of a patient to the hospital.

It is the responsibility of the case for admission, and also, in the event of the patient's death, to the family, it would render the hospitals liable to meet outlays for which there was no financial provision. It suggests that in any contributory scheme, the presence, limitations, or absence of a contractual obligation for the provision of hospital and additional benefits should be plainly stated to the contributors. The scheme at this hospital implies no contract on the part of the hospital to provide such institutional benefit as the subscribers may require. Under its provision a weekly contribution of 2d. exempts the contributors from the patients' payments due from non-contributors. In the case of married people, where the husband and wife each subscribe 2d. a week, their children are also entitled to treatment up to wage-earning age, and from then until they are earning adult's wages each child pays 1d. a week. The children of a widow or widower are also entitled to treatment up to wage-earning age on the 2d. contribution of their parent. Non-contributors are required to contribute towards their maintenance in the hospital, but no payment is required from old-age pensioners or others quite unable to pay.

It is definitely pointed out on the card which is issued to all subscribers of weekly contributions that every case must be accepted by the physician or surgeon of the hospital as suitable for hospital treatment. Contributors are specially requested to bring a letter from their doctors. It is pointed out that it must be clearly understood that only those who, owing to the gravity of their illness, and on account of their financial position, are unable to obtain adequate medical and surgical treatment, are entitled to attend at the hospital. The hospital strives by every means in its power to prevent all abuse, and up to the present we have had only one complaint from a doctor in the area that his practice had been injured. On the other hand, members of the staff are frequently urged by medical practitioners in the neighbourhood to admit patients who are seriously ill or require an immediate operation. We have established 270 hospital aid committees in

the villages and thirteen in the market towns. These committees arrange for the collection of the payments and remit them to our hospital once a quarter. We know that we have now some 4,000 helpers, directly interested in our hospital, knowing something of the work it is doing, and most anxious to keep it in full working order. And we not started this scheme we should have been compelled to close down more than half our beds for want of funds. The question of a staff fund has been carefully considered by the staff and unanimously and emphatically rejected.

IV.

ARRANGEMENTS IN BRISTOL HOSPITALS FOR RECEPTION OF PAYING PATIENTS.

[For the following contribution we are indebted to Dr. J. A. Nixon, C.M.G., physician to the Bristol Royal Infirmary, who has had valuable assistance, in checking the information, from Mr. E. C. Smith, the secretary of that institution.]

The Report on the organization of voluntary hospitals and the reception of paying patients, published in the SUPPLEMENT to the BRITISH MEDICAL JOURNAL of February 25th, will shortly be considered by the Divisions, and then again by the Council before its presentation to the Annual Representative Meeting. The following account of measures adopted last year in Bristol contains data that may be of general interest and prove useful in future discussions. In May, 1921, the Governors of the Bristol Royal Infirmary and General Hospital adopted a scheme for the admission of paying patients to the two voluntary hospitals. The scheme, which came into operation on July 1st, was a uniform one, agreed to by the committees and staffs of both institutions after a series of conferences held in common.

All in-patients with the exception of really necessitous cases should be asked to pay one guinea per week towards the cost of their maintenance. All out-patients and casualties, except the necessitous poor, should be asked to pay a registration fee of sixpence per attendance, and also an extra sixpence for medicines or dressings when supplied, and a special charge should be made for treatment by x rays, electricity, massage, etc., according to cost.

Each institution should appoint its own almoner or inquiry officer. The medical staffs, realizing that the adoption of this scheme involved a fundamental change in the conditions under which they would be working, made a definite offer to alter the terms of their service, and this offer being accepted by the governors constitutes a new and definite contract between the governors and the staffs. The offer was as follows:

In order to enable the governors to bring into operation the proposals for the admission of paying patients, the honorary staff desire to offer their gratuitous services to all patients who are found after inquiry by the almoner to be unable to pay more than the cost of their maintenance. But in the case of patients whose payments are defrayed by public authorities or approved societies the honorary staff will attend and treat such patients in consideration of an agreed percentage of the gross payment received by the hospital being allocated to and paid into a fund which shall be administered by the honorary staff.

The plan has been working for a little more than six months. The effects at the Royal Infirmary have been analysed carefully. As regards the admission of in-patients, no perceptible variation has been recorded; the number of out-patients may have declined a little, but as previous records deal with a full year instead of six months, the secretary is inclined to think that there will be no material alteration in a year's totals. The casualties and emergencies have, on the other hand, dropped by one-fifth, an effect which the secretary considers is directly due to the small charge made, but he points out that formerly people would come in to have the most trifling cuts and abrasions dressed, and it is their abstention which has reduced the figures.

The financial workings of the scheme are worthy of note. The average stay of each in-patient was two and a half weeks, and the number of in-patients was 2,684; if each of these patients had paid one guinea a week whilst in hospital a sum of 6,710 guineas (£7,045) would have been received. The actual number of in-patients who paid 1 guinea was 456; 330 paid from 10s. to £1; 494 paid under 10s.; and 789 were passed free. From out-patients, if one shilling had been paid for each attendance the sum of £4,325 would have been received (29,000 out-patients attended, with an average of three and a half attendances per case).

The actual sum received from both in- and out-patients was £2,969 instead of £11,375. The conclusion is that only one patient in five was found by the almoner to be in a position to pay the full sum asked for. Smaller amounts were accepted than the full sum, but it must be observed that the one guinea per week in-patients are asked to contribute is only about

one-third of the actual cost of maintenance. The almoner at the Royal Infirmary is an experienced lady, well qualified for the work, whose competence to assess a patient's circumstances no one questions. It seems clear that the amount which patients can contribute to the cost of hospitals is so little as to provide no solution of the financial difficulties with which they are faced.

Another result must be mentioned. Formerly considerable sums were paid by collections among works employees. The money when collected was paid over to the hospitals. Now in many instances the money is held in a "works fund," and expended as occasion arises to defray the hospital charges of such contributors to the fund as chance to need hospital treatment. There has not yet been time to say whether the hospital gains or loses by this arrangement.

But, looked at from any point of view, there appears no prospect that patients' contributions can furnish adequate financial support for hospitals unless the hospitals are diverted from their original object of catering for the poor and are open only to those who can pay for admission.

Other voluntary hospitals in Bristol are making trial of the same scheme. The Bristol guardians have also introduced a plan for the admission of paying patients to the Poor Law hospital at Southmead. The following rules are in force:

Admission of Private Patients to Southmead Infirmary.

Paying patients may, at the discretion of the Infirmary Committee, be admitted for treatment or operations when the accommodation there admits.

Cases only will be entertained which need infirmary treatment, and which, on investigation, are found to be quite unable to pay the rates of charge made at private nursing homes or other available institutions.

Applicants must, in the first instance, produce a certificate of recent date from a medical man who has been attending the case within one month from the date of the application, such certificate to fully state the nature of the illness and, in the case of an operation considered necessary, the nature of the operation.

The weekly charge for ordinary treatment will be £2 2s. in one of the general wards or £3 3s. per week where a single-bed ward or bed in a three-bed ward is required. This charge to include attendance from the infirmary resident medical staff. In the event of the services of one of the consultant medical officers of the infirmary being required an additional charge of £1 ls. for each attendance of the consultant shall be paid, and in the event of an operation being required a fee shall be paid for the services of the operating surgeon at the rate specified in the table attached hereto.

The private medical attendant of a patient so admitted may be allowed, subject to reasonable restrictions, to visit him in the infirmary and confer with the medical staff in reference to his progress.

All applications for admission must be made to the clerk to the guardians.

It will be noticed that the guardians have not seen their way to consent to paying patients remaining under the entire charge of their own doctors when admitted to Southmead. They put the matter clearly when they said that they did not think that the regulations at present governing the administration of Poor Law infirmaries would permit them to run a private nursing home where the doctors in attendance on the patients would not be in any sense responsible to the board of guardians.

The admission of paying patients is in the hands of the clerk to the guardians, and is outside the province of the relieving officers.

V.

BY A MIDLAND GENERAL PRACTITIONER.

The organization of voluntary hospitals is so intimately bound up with the teaching and practice of medicine that any alteration or suggested alteration in their organization or work is bound to arouse the strongest interest all through the medical profession. The fact that the Council of the British Medical Association has thought it necessary to issue a special report on this subject in advance of the usual annual report of the Council, and to lay down a proposed policy for the Association, is evidence that alterations of serious and fundamental character are actually taking place or expected to take place.

A consideration of these changing conditions shows that they are being brought about by the progress of medicine and surgery are making in their methods of diagnosis and treatment; they do not originate primarily in a change of the attitude of the public towards the hospitals or even in a change of the public mind. With the progress of scientific

knowledge more and more expensive means both of diagnosis and treatment are being evolved and taking their place in the scheme for dealing with diseases of all kinds.

The immediate effect of this is that a continually increasing proportion of the whole population find themselves unable to provide what is now considered necessary for their proper treatment without having recourse to the hospitals, either because the treatment is beyond their reach financially or because the apparatus is not otherwise available, and an increasing proportion of all diseases are more efficiently treated in hospital than they can possibly be in the homes of the patients.

In London and the large centres with teaching schools this same progress leads to a continually increasing degree of specialization among the members of the staffs of the voluntary hospitals, and an increasing gap between the experience of the specialists and that of the great body of the practising medical profession. Even thirty years ago, outside London, a large proportion of the consulting physicians and surgeons on the staffs of the voluntary hospitals were at the same time in general practice, and appointments to the hospital staff were within the reach of suitably qualified general practitioners. These conditions still hold in the smaller centres and with regard to the staffing of county and other voluntary hospitals. And in country districts the cottage hospitals give practitioners an opportunity of keeping up certain sides of their work. The town general practitioner is in danger of becoming a sorting and certificate-signing machine, passing all important treatment on to others (because it is in the best interest of the town patient), and having no opportunity of carrying out or seeing carried out such treatment.

The absolute necessity of linking up the general practitioner of the town with the treatment carried out in voluntary hospitals, if he is to maintain and increase his efficiency; must not be lost sight of in the changes of organization which are taking place. This can be helped in several ways—for example, by the frequent holding in the hospitals of clinical courses of instruction for practitioners, by the establishment of small hospitals or setting aside wards in hospitals, in which, as in the present cottage hospitals, the practitioner can take his part in the treatment. The increasing cost and complexity of medical treatment is taking to the voluntary hospitals numbers of persons who must get their treatment in this way, although able and willing to pay something of the cost. In the past these people have paid their own doctors', and in many cases the consultants', charges, and this money is part of the available income which enables an area to provide and pay the number of medical practitioners of the various types necessary for the medical service of the inhabitants of the place. If the voluntary hospitals, out of subscriptions and charitable funds, are to provide services for these persons free of cost, much harm is likely to be done to the medical service of the district; as the available money for medical services gets less the number of practitioners would proportionally diminish.

For these reasons it seems essential that, in any changes of organization by which certain patients pay the hospital for the benefits they receive, and if the standard and amount of medical service in the area is to be maintained, payments must be made to the practitioners who carry out the treatment. As a temporary measure, and as the only practical way yet put forward, the staff fund does meet this point. The staff fund ought not to be regarded as the final settlement of this difficult question, but only as a present and temporary solution during what is likely to be a transition period.

For the sick poor, in the future as in the past, the services of the medical profession, both consulting and general practitioner, will be certain to be available. It is a tradition we have inherited and which we would wish to pass on to our successors unimpaired, and it is our business to see that changes in organization do not interfere with this principle.

Of the many and various expedients to which the voluntary hospitals have resorted to increase their funds there is one that concerns the medical profession most closely. I refer to the recent schemes for enrolling members who, in return for a weekly or other periodic payment, are entitled to the services of the hospital when they may require them; in other words, "hospital clubs." The method of regular collections from workers to Hospital Saturday Funds, which are handed over to the hospitals as donations, has been found in practice to carry with it an implication of right to service by the subscribers, so that these donations tend to become

payments for services; but this implication is as nothing to the obligation which a hospital will find itself saddled with when it starts its "hospital club." The members of the scheme can and will demand hospital treatment whenever they consider they require it, and will not tolerate rules which would limit their access to the hospital—for example, via the general practitioner's recommendation. Such a club, if successful, would quickly monopolize the resources of the hospital, and the staff of consulting physicians and surgeons would find themselves engaged in a new form of club practice in which they did not even get the small weekly subscriptions. Fortunately this type of scheme is not likely to succeed.

One of the most recent phases of the hospital problem has arisen from the attempts which some approved societies have made and are making to give additional benefits to their members in the form of the services of consultants, or of specialists in some particular subject—for example, ophthalmic surgeons. The medical profession had always anticipated that when such benefits were added to the present general practitioner's service the scheme would be drawn up by the Ministry in consultation with the profession, and not in the way that it is coming about now. In face of this it is of primary importance that the medical profession take up the position at once that any society wishing to extend to its members any service by registered medical practitioners must negotiate its scheme direct with the profession through the British Medical Association and not with the committees of voluntary hospitals; and that negotiations with the hospital authorities should only take place after it has been agreed that the service in question would be given to greater advantage through a voluntary hospital than by the individual practitioner. It should be brought to the knowledge of societies that the British Medical Association is willing to help them to lay out their schemes on the best lines, and hospital staffs should be warned not to agree to give service under any such arrangements as have not been approved centrally as well as by the profession locally.

Though many or most of us would prefer to see the old arrangements of voluntary hospitals and their honorary staffs carried on unaltered, yet the changes now coming about seem to render this impossible, and it is not in the interest of either the public or the voluntary hospitals that we should allow fresh arrangements to mature without expressing our opinion on the form these arrangements should take.

VI.

BY A LONDON GENERAL PRACTITIONER.

MOST of the present turmoil in the medical profession, as well as amongst the public, is due to the contest between the principle of voluntary effort and the principle of State control.

If it be agreed that the State, through local authorities, should make complete provision for the medical treatment of some section of the community (if not the whole), it becomes plain that the two services which urgently require consideration at the present moment are the hospitals and the clinics. In connexion with these services certain axioms may be laid down. In the first place, in the present state of the country's finances economy is necessary. If any advocates of those services desire particular modifications it is essential that these modifications should be shown not only to make for efficiency, but also to be economical. A very high degree of efficiency will be required to justify the more expensive of two methods. It is not to be expected that local authorities will double the expenses simply to oblige the medical profession. Secondly, as public funds will be involved, the usual corollary of public control will be insisted upon. Thirdly, in order to enforce public control all medical officers engaged in the service will be paid. Fourthly, sooner or later in any service involving any special skill the public authority will insist on the production of credentials.

If local authorities become responsible for hospital treatment there are various methods by which it may be exercised. Thus, arrangements may be made with a voluntary hospital if such exists with a sufficiency of beds. In this case the voluntary hospital could retain its distinctive character, and might receive payment from the local authority in return for right of inspection of their patients under treatment, or for some representation on the hospital board, or both. But if all patients of the hospital class become the care of the local

authority, it is clear that in the end the local authority will have a preponderating voice in the management of the hospital, and the voluntary hospital system will become extinct. Hence again the need for answering fundamental questions becomes clear. For what sections of the community should the State make complete provision? Instead of making arrangements with voluntary hospitals, and in places where no such hospitals exist, the local authority might set up hospitals of its own or utilize existing Poor Law infirmaries, as is indeed being done.

Much is made of the stigma of pauperism. But in its essence is there any real difference between the municipal hospital and the Poor Law infirmary? Both are under public bodies; both take people who cannot afford adequate treatment at their own expense; both have the right to make a charge according to the means of the patient; to both certain sections (if not the whole) of the community have the right of admission under certain circumstances; in both treatment is conducted by paid servants of the authority. The only possible differences will be in matters of detail, and in the fact that the right of admission to these institutions is to be extended to cover a larger section of the community.

It is at this point that the views of the Consultative Council of the Ministry of Health come into prominence. Is it possible to make these municipal hospitals correspond to the Primary Health Centres of the Dawson Report? In certain areas perhaps; in other areas almost certainly not. The present Poor Law infirmary is generally a large institution wherein are many cases of serious illness. In the past treatment has, in the main, been carried on by whole-time medical officers who in many instances acquired skill and experience. This position is now changing. Consulting staffs have been appointed to some infirmaries in various parts of the country, and the proposals of the Ministry of Health will lead to these institutions being thrown open to other grades in the community. The Primary Health Centre, it has been proposed, should be an essential part of general practitioner treatment. Are these large infirmaries, which are now introducing more specialized work, to be handed over to the general practitioners in the districts in which they are situated? If all the general practitioners of the area are to be admitted to treat their patients in the infirmary, what is to be the relation of the whole-time superintendent to all the general practitioners? Under what supervision or inspection will the local authority which pays for the infirmary place the general practitioners who are treating patients for whom the authority is responsible? When the municipal hospital takes the form of a cottage hospital, all may be well. In an outlying suburb of manageable dimensions, or in a comparatively small special hospital, some reasonable arrangement may be made. But these are "parish pump" concerns compared with the disposal of a municipal hospital of 2,000 beds. And it is in terms of such institutions that the questions should be debated.

In connexion with the formation of municipal hospitals there is another matter which has received insufficient attention. There has long been an outcry against the so-called out-patient departments at voluntary hospitals. In schemes drawn up by the British Medical Association there has usually been a statement to the effect that there shall be no out-patient departments of municipal hospitals. But a very large number of patients go to out-patient departments, and the question is whether the medical profession can at the present time absorb these patients so that these departments shall cease to exist. For financial reasons an extended panel system applying to the dependants of insured persons is probably out of the question at present. A large proportion of the hospital out-patients are unable to pay a fee at which the private practitioner is willing to see them. They are of value for teaching purposes where medical schools exist. Their numbers are, as a matter of fact, being added to in the system of clinics which are now springing up—as, for example, at Willesden. The method by which some of the class are being treated by the guardians through district medical officers does not seem satisfactory in some areas. On the other hand, a system of driving them to seek medical treatment from private practitioners might ultimately tend to solve the question by producing an additional crop of doctors willing to take on such work. At all events, I venture to suggest that the question does not seem to be so completely settled as to justify the dictum "no out-patient departments." Active local authorities will establish such departments unless their difficulties are met by reasonable discussion. If it can be shown that the local provision of

medical man-power is adequate for the purpose, both in quality and quantity, there is no reason why out-patient departments should not be curtailed. Until this is shown it is probably better in certain districts to concentrate on a proper sifting of cases by means of almoners.

In regard to health measures for the future it would be well if three questions were definitely answered before any further legislation is attempted: First, is it agreed that the State, through local authorities, should make complete provision for the medical treatment of the community, or for any section of the community? Secondly, if it is thought that only partial provision should be made, in what should that provision consist? Thirdly, if provision is not to be made for the whole community, to what section should it be limited? To these fundamental questions a fourth may be added—namely, in what way should the cost of these services be defrayed? This question can only be answered after details of the proposed services have been fully considered.

THE METRIC SYSTEM IN MEDICINE.

THE advantages of employing the metric system for prescribing is a matter which has long been under the consideration of the medical profession in this country, and particularly of the British Medical Association. The Medico-Political Committee of the Association, so long ago as 1908, in a report to the Annual Representative Meeting at Sheffield, advocated its introduction, and recommended that a pronouncement should be made on behalf of the Association in favour of the principle of its adoption. Dr. R. C. Buist suggested a practical method of effecting a transition to the metric system in prescribing and dispensing, and this was duly considered and reports were made to the Divisions, leaving it to each Division to take such further action as it deemed advisable. It was agreed at that time by the Representative Meeting that the metric system was safer so far as prescribing was concerned, that its adoption was simple, and that the retention of the present system was unjust to the rising generation of medical students and chemists.

In 1911 the Council of the Association, in pursuance of the instructions of the Annual Representative Meeting at Sheffield, issued a special report on the adoption of the metric system of weights and measures by medical practitioners in prescribing and dispensing. In this report it was stated that the full and complete adoption of the metric system in practice depended upon its being made the system according to which students were trained, so that they would learn to think of quantities primarily in terms of grams, centimetres, etc., instead of, as at present, grains, minims, etc. The Council therefore recommended that the teaching, both theoretical and practical, in pharmacology and materia medica should henceforth be according to the metric system. In 1913 the Medico-Political Committee of the Association again considered the matter in view of the official recommendations by the General Medical Council, but resolved to take no further action at that time. The employment of the metric system in prescribing and dispensing came up again at the Annual Representative Meeting in July, 1917, when a motion was adopted to the effect that the general use of the metric system in the teaching of dispensing, prescribing, and treatment would be beneficial to the scientific interests of the medical profession, and this resolution was forwarded to the General Medical Council, the universities, and other interested bodies.

In spite of these recommendations, however, it must be confessed that the use of the metric system has not yet made much progress among the general body of the medical profession in this country. If, however, medical students are trained thoroughly in its employment, the general adoption of the metric system by the profession must come in time.

At a meeting of the North British Branch of the Pharmaceutical Society of Great Britain, held at Edinburgh on February 15th, 1922, Dr. W. C. Sillar, lecturer on experimental pharmacology at Edinburgh University, stated that the question of employing the metric system for prescribing had been forced upon their attention at Edinburgh by circumstances due to the war, which rendered it necessary to lighten the curriculum. Instead, therefore, of teaching two systems of prescribing, and letting the individual student exercise his preference, the relative advantages and disadvantages were weighed, and the metric system alone was chosen for instructing students. The student, appreciating the ease

of calculation of the metric system and its simplicity, met with no difficulty until he encountered his clinical teachers, and was obliged to follow their instructions in the other method. The practitioner, who had learned his doses in minims, grains, and drachms, and was unable readily to translate from one system to the other, was apt to exaggerate the difficulties. The difficulties of the pharmacists were the expense of weights and measures, or alternatively of errors in reading or transposition of quantities from the one system to the other. The imperial system, modified for prescription writing by the additional use of the apothecaries' weight, owed its persistent use to certain conveniences which it possessed. The weights and measures of the system were mainly those which had been originally convenient domestic measurements; for instance, the handful was represented by the ounce, the drop by the minim, the mouthful by the fluid ounce, the teaspoonful by the fluid drachm, a drink by the pint. Secondly, the relation between the weights, as well as that between the measures, had been arrived at to a considerable extent by the simple process of successive doublings; the imperial ounce doubled successively four times equalled the pound, and the apothecaries' drachm doubled successively three times was the apothecaries' ounce. Thirdly, the dissimilarity between the names of these various increments lessened the likelihood of confusing them with one another. The advantages of the metric system, on the other hand, consisted in the easy divisibility by tenths and the simple interchange into equivalents between the respective weights and measures. The advantages of both systems could be combined to some extent for prescription writing by visualizing the fluid domestic measures, the teaspoonful, etc., by the nearest metrical equivalent, 5 c.cm., and then doubling; thus, 5 c.cm. was approximately equivalent to a large teaspoonful, 10 c.cm. to a large dessertspoonful, and 20 c.cm. to a large tablespoonful. This principle might also be carried out with the present conception of the unit to represent the grain, which might therefore be taken as 0.05 of a gram. Two grains and four grains presented no difficulty, being 0.1 and 0.2 of a gram respectively, but the discrepancy became marked on arriving at 10 grains. Therefore in deciding on dosage the new departure had to be made, and it must be considered whether 1.0 gram was too large a quantity or 0.5 too small. Confining the figures to 1, 2, and 5, the question of symbols and nomenclature might also be simplified. To prevent errors in placing the decimal point, a perpendicular line should be drawn immediately to the right of the whole numbers; the use of the decimal point was then no longer necessary. Solids were to be weighed and fluids to be measured, percentages were to be expressed by the weight of a solid in the volume of a fluid, and in the case of fluids by volume in both.

Dr. Sillar said that his practical classes had done the whole of their dispensing using weights of grams and fractions of grams and graduated measures of 100 c.cm., 10 c.cm., and 1 c.cm. He hoped that the medical and pharmaceutical professions would heartily co-operate in this serious attempt to lessen the burden of the medical student and to carry out the recommendation of the General Medical Council.

THE late Dr. Alfred Mason, O.B.E., M.C., Admiralty surgeon and agent for Deal, has left net personalty of £13,831. He bequeathed, subject to two life interests of two aunts, £1,000 to the Royal Medical Benevolent College, Epsom, for the education of sons of deceased medical men, to be known as the "Caroline Mason Bequest."

THE sixth Unity History School will be held at Woodbrooke, Birmingham, from July 27th to August 4th. The special character of these schools is the mingling of classes; teachers, business men, labour leaders, professors, and working men attend, and the discussions after the lectures, of which one is given each day, are carried on with good humour and good taste by all parties. This year the course of lectures arranged by Mr. F. S. Marvin and Dr. Charles Singer will deal with "Science and Social Progress," and each will be given by an authority on the subject. Thus, of two lectures on the science of the Greeks, one on biology will be given by Mr. J. A. Platt, Professor of Greek in University College, London; Dr. Singer will lecture on "The Dark Ages and the Dawn," Professor J. A. Thomson on "Darwinism and Contemporary Life and Thought," and Mr. Julian Huxley of Oxford on "Science and Religion." Other lectures, on the relation of science to everyday life, will be given by various authorities. Full particulars can be obtained from Mr. Edwin Gilbert, 78, Mutley Plain, Plymouth.

CURRENT NOTES.

Hospital Policy: Conference of Representatives of Voluntary Hospitals.

Change of Place of Meeting.

WITH reference to the Current Note published in last week's SUPPLEMENT, attention is directed to the fact that, in view of the number of representatives of medical staffs of voluntary hospitals invited to the Conference, it has been found necessary to engage a larger hall. The Conference on March 22nd, 1922, will accordingly be held in the Wigmore Hall, 36, Wigmore Street, London, W.1. A preliminary notice and invitation has been issued to the medical staffs of all hospitals in England and Wales, and the basis of representation has been fixed as one representative for hospitals of 100 beds or less and two representatives for hospitals of over 100 beds. It is urged that medical staffs should seriously consider the report on hospital policy which has been issued with the preliminary notice. It was published in the SUPPLEMENT to the BRITISH MEDICAL JOURNAL of February 25th. Medical staffs are asked to forward to the Medical Secretary of the Association the names of their representatives at the Conference, and any motions or amendments for consideration, so as to reach the office of the Association not later than the first post on Tuesday, March 14th, 1922. No representative will be admitted without a ticket of admission, which will be obtainable from the Medical Secretary of the Association, 429, Strand, W.C.2.

Ministry of Pensions Medical Officers.

IN March, 1921, the whole-time medical officers of the Ministry of Pensions secured an agreement with the Ministry as to their salaries. They had for some time been pressing either for bonuses such as had been given to other temporary civil servants, or for an increased fixed salary. The result was that the Ministry declined to give bonuses, but made agreements, either for four years or for six months, at salaries which ranged between £800 and £1,200 a year. The medical officers quite naturally assumed that, bonuses having been refused and a fixed salary given, they were safe for four years or for six months as the case might be, but they have recently been called upon to undergo a reduction of their salaries. It is understood that they have met the Minister by reputation, and he has agreed that there shall be no change for the next six months, but that at the end of that time the position shall be reconsidered. The ordinary person finds a difficulty in understanding why people who so recently got what they believed to be a definite agreement should be called upon to undergo a reduction either now or in six months' time. But apparently Government departments are not bound by considerations which affect an ordinary employer, and it looks as if they were able to override the law of contract as generally understood. The action of the Minister will be watched not only by the medical officers concerned but by all those who still have some regard for the honourable observance of an understanding once reached.

Clerical and Travelling Expenses of Medical Officers of Health.

IN a Current Note under this heading in the SUPPLEMENT of January 7th it was pointed out that the Port Talbot Town Council had been advertising for a medical officer of health, and that one of the conditions of appointment was that he should pay for clerical assistance and travelling expenses out of his salary. Steps were taken which resulted in the withdrawal of this condition, but it is understood that several appointments are likely to be made shortly in which the appointing authorities intend to try to throw the payment of official expenses on the holder of the appointment. This is a thoroughly bad principle. It may lead either to the officer cutting down his travelling expenses and correspondence or other official expenses to a point which may be incompatible with efficiency, or, if he is a conscientious man, it may lead to encroachments upon his salary to a point which is not fair to himself. It should be made perfectly clear that, so far as the BRITISH MEDICAL JOURNAL is concerned, no advertisements will knowingly be accepted in which the remuneration is a gross salary out of which the medical officer is expected to pay any official expenses. The Medical Secretary will be glad to be informed of any appointment pending in which such conditions are likely to be offered.

Insurance Certificate Books.

MEDICAL practitioners are asked to note that the price of the books of 50 *National Health Insurance Certificates*, published by the British Medical Association, is now 9d. (post free), and not 6d. as formerly. The form of certificate has been altered so as to conform to the form of certificate recently issued by the Ministry of Health. It is intended for use by practitioners when attending insured persons who are not their panel patients, and who are not persons whom they are attending as medical officers of institutions under Section 15 (4) or in virtue of "own arrangements" under Section 15 (3). Applications for the *Certificate Books* should be addressed to the Financial Secretary, 429, Strand, London, W.C.2.

Meetings of Branches and Divisions.

BIRMINGHAM BRANCH: WEST BROMWICH DIVISION.

A MEETING of the West Bromwich Division was held on February 23rd. Dr. Stocks having intimated that he will be unable to attend the Annual Representative Meeting at Glasgow, Dr. L. A. Dingley was appointed to fill his place. The question of the suggested separation of the Smethwick members was again discussed. It was arranged that the subject be brought up at the next meeting of the Smethwick Panel Committee in order to get the views of the Smethwick members themselves.

ESSEX BRANCH: MID-ESSEX DIVISION.

A MEETING of the Mid Essex Division was held at Chelmsford on February 22nd. The following officers were elected:

Chairman: Dr. P. T. Spencer-Phillips. Vice-Chairman: Dr. H. Reynolds Brown. Honorary Secretary, Treasurer, and Representative on Branch Council: Dr. H. G. L. Haynes.

The meeting, which was attended by members and visitors from all parts of Essex, afterwards listened with considerable interest to an address from Dr. Cox, the Medical Secretary. An interesting discussion was subsequently held on several points of importance.

METROPOLITAN COUNTIES BRANCH: WILLESDEN DIVISION.

A MEETING of the Willesden Division was held at St. Andrew's Parish Hall, N.W., on February 21st. The Honorary Secretary stated that the correspondence between the Division and the Urban District Council had been laid before the Minister of Health. A letter from the local Urban District Council was read, which stated that the memorandum of the Division (adopted at the last meeting) as to the health services question would be submitted to the Health Committee in due course; 35 copies of the memorandum were asked for and had been supplied.

A letter from the Medical Practitioners' Union was read asking for the advice of the local profession with respect to the health policy of the local Urban District Council prior to a deputation from that body waiting upon the council. The Honorary Secretary stated that a deputation of the Medical Practitioners' Union, consisting of Drs. Ward, Gregg, and Weply, had attended at his house before waiting upon the local town council, and had an interview with the chairman of the Division, Dr. Skene, and Drs. Lock, T. Smith, and himself, when an interesting discussion had taken place; the Union representatives said that they would not claim at the interview to represent the local medical profession.

The Chairman and Honorary Secretary were appointed to attend (by invitation) a meeting of the North Middlesex Division on March 1st, for a discussion on the question of treatment centres.

A report was received by the Secretary: (i) that Dr. Sturridge had been invited by the local branch of the Red Cross Society to attend a meeting in connexion with the establishment of a V.A.D. clinic and orthopaedic centre for children; (ii) that he had advised Dr. Sturridge to attend the meeting; and (iii) that subsequently the president of the local Red Cross Branch had discussed the question with him, when he had deprecated any action being taken in the matter. The Honorary Secretary's action was approved.

YORKSHIRE BRANCH: SCARBOROUGH DIVISION.

An ordinary meeting of the Scarborough Division was held at the Pavilion Hotel on March 2nd.

Dr. SINCLAIR MILLER, D.S.O., M.C. (Clinical Laboratory, Harrogate), read a very interesting paper entitled "The clinical application of vaccines and serums." A lengthy discussion of some of the most important points in the paper ensued, in which Drs. HORNLEY, SALTER, WIGHTMAN (Scalby), CURT, SIMPSON (Harrogate), DICK, FERGUSON, and ROBERTSON took part.

On the motion of the Chairman, Dr. THORNLEY, seconded by the Vice-Chairman, Dr. HANDBOCK, a hearty vote of thanks was accorded to Dr. Miller for his paper.

Association Notices.

TABLE OF DATES.

Mar. 15, Wed.	Branch Reports for 1921 due to Head Office on or before this date.
April 1, Sat.	Nomination papers available at Head Office for election of 24 Members of Council for 1922-23, by grouped Home Branches.
April 26, Wed.	Council Meeting, 429, Strand, at 10 a.m.
April 29, Sat.	Last day for receipt at Head Office of Independent Motions for Annual Representative Meeting Agenda, as to policy, Articles, or By-laws (By-law 40).
May 6, Sat.	Annual Report of Council appears in SUPPLEMENT.
May 8, Mon.	Last day for receipt at Head Office of Nominations, by a Division or not less than 3 Members, for election of 24 Members of Council by grouped Home Branches for 1922-23.
May 13, Sat.	Publication in SUPPLEMENT of list of nominations for election of 24 Members of Council by grouped Home Branches for 1922-23.
	Voting papers for election of 24 Members of Council by grouped Home Branches posted from Head Office to Members of groups where there are contests.
May 27, Sat.	Last day for receipt at Head Office of voting papers for election of 24 Members of Council by grouped Home Branches (where there are contests).
June 3, Sat.	Publication in SUPPLEMENT of results of Council elections by grouped Home Branches.
June 10, Sat.	Nomination papers available, at Head Office, for election of 12 Members of Council by grouped Home Representatives.
June 14, Wed.	Council Meeting, 429, Strand, at 10 a.m.
June 23, Fri.	Last day for election of Representatives and Deputy-Representatives.
June 24, Sat.	Supplementary Report of Council appears in SUPPLEMENT.
June 30, Fri.	Last day for receipt at Head Office of notification of election of Representatives and Deputy-Representatives.
July 7, Fri.	Last day for receipt at Head Office of Amendments and Riders for Annual Representative Meeting Agenda.

ALFRED COX,
Medical Secretary.

ELECTION OF MEMBERS OF COUNCIL BY
BRANCHES OUTSIDE THE UNITED
KINGDOM.

The following is the result of the election of Members of Council for 1922-23 (unless otherwise stated) by Branches outside the United Kingdom, only one nomination being received in each group:

- Mr. T. P. DUNNILL, C.M.G., London. South Australian, Tasmanian, Victorian, and Western Australian Branches.
Sir JENNER VERRALL, LL.D., Leatherhead (elected in place of Dr. H. A. Francis, resigned—for years 1921-23). New South Wales and Queensland Branches.
Dr. DAVID EWART (elected for years 1920-23). New Zealand Branch.
No nomination. Barbados, Bermuda, British Guiana, Grenada, Halifax (Nova Scotia), Jamaica, Leeward Islands, Montreal, St. John (New Brunswick), Saskatchewan, Toronto, and Trinidad and Tobago Branches.
Lieut.-Colonel R. H. ELLIOT, I.M.S. (ret.), London. Assam, Baluchistan, Bombay, Burma, Ceylon, Hyderabad and Central Provinces, Punjab, and South Indian and Madras Branches.
Dr. NOEL CLARKE, Singapore. Hong Kong and China, and Malaya Branches.
Dr. T. DUNCAN GREENLIES, Fordingbridge, Hants (for years 1922-23). Border (South Africa), Cape of Good Hope (Eastern), Cape of Good Hope (Western), East Africa, Gibraltar, Grignaland West, Malta, Natal Coastal, Natal Inland, Nyasaland, Orange Free State and Basutoland, Pretoria, Rhodesia, Uganda, and Witwatersrand Branches.

BRANCH AND DIVISION MEETINGS TO BE HELD.

LANCASHIRE AND CHESHIRE BRANCH: SOUTHPORT DIVISION.—The B.M.A. Lecture by Dr. A. Burrows on "Radium Therapy," postponed from February 16th, will be delivered on Thursday, March 23rd.

METROPOLITAN COUNTIES BRANCH: CITY DIVISION.—The next Divisional meeting will be held at the Metropolitan Hospital on Friday, March 17th, at 9.30 p.m., when Mr. G. T. Loughborough, Surgeon-in-Charge of X-ray Department, will give an address on "The X-ray Examination of the Stomach," illustrated by lantern slides and skiagrams.

METROPOLITAN COUNTIES BRANCH: WESTMINSTER AND HOLBORN DIVISION.—The annual general meeting of the Division will be held at the Trocadero Restaurant on Thursday, April 6th, at 8.45 p.m. The meeting will be preceded by dinner at 7.30 p.m. At 9 p.m. Dr. Leonard Williams will read a paper on Interstitial Glands, and a discussion will follow. Members and non-members are cordially invited to dinner, or the meeting, and are requested to communicate with the Honorary Secretary, Dr. F. D. Bennett, 18, Savile Row, W.1.

NORTH OF ENGLAND BRANCH: NEWCASTLE-UPON-TYNE DIVISION.—A meeting of the Newcastle-upon-Tyne Division will be held at the Medical Institute, 7, Windsor Terrace, on Tuesday, March 14th, at 7.30 p.m. Appointment of Representatives for Annual Meeting. Discussion on "The Organization of Voluntary Hospitals" opened by Mr. F. C. Pybus and Dr. James Hudson. If time permits the evening will terminate with an informal social gathering, at which light refreshments may be obtained.

NORTH WALES BRANCH.—The spring meeting of the North Wales Branch will be held at Wrexham on Tuesday, April 4th.

SUFFOLK BRANCH: SOUTH SUFFOLK DIVISION.—The annual general meeting of the South Suffolk Division will be held at the Crown and Anchor Hotel, Ipswich, on Friday, March 24th, at 3.30 p.m. Agenda: Election of Officers Hospital Policy. (A) Communication from the Medical Secretary enclosing A.R.M. 2 (b) SUPPLEMENT to the BRITISH MEDICAL JOURNAL, February 25th, 1922, containing Report of Council on the Organization of Voluntary Hospitals, and the reception of paying patients. (Members are requested to bring SUPPLEMENT to the meeting.) (B) Report from the Medical Staff of the East Suffolk and Ipswich Hospital on this matter. Scheme for collective arrangements for locumtenencies (see SUPPLEMENT, December 24th, 1921).

WORCESTERSHIRE AND HEREFORDSHIRE BRANCH.—A meeting of the Worcestershire and Herefordshire Branch will be held at Great Malvern on Thursday, April 27th, when a B.M.A. Lecture will be given by Professor G. R. Murray on a subject connected with internal secretions.

WILLESDEN HEALTH POLICY.

A communication has been received by the Medical Association from the Clerk of the Willesden Urban District Council:

"I am directed to acknowledge receipt of your letter dated 18th January, 1922, enclosing a further memorandum on the Willesden health service. The Council note that the British Medical Association, Willesden Division, while welcoming the suggestion, do not take advantage of the offer of the Council, contained in paragraph 18 of their letter of the 21st December, 1921, to consider any scheme which the British Medical Association, Willesden Division, may care to put before them for working the Willesden Municipal Hospital and Clinics. In the absence of such alternative proposals the Council beg to inform the Division that they have nothing to add to the previous communications."

DENTAL BOARD OF THE UNITED KINGDOM.

At the last meeting of the Dental Board of the United Kingdom, held at 44, Hallam Street, W., on February 14th, 1922, with the Right Hon. F. D. ACLAND in the chair, a communication was read from the Privy Council notifying approval of the Regulations adopted by the Board on December 9th last, under Section 7 of the Dentists Act, 1921. The letter ended as follows:

"As regards Chapter 5 of the Regulations—'The Prescribed Examination'—I am to take this opportunity of stating that their Lordships would deprecate the enforcement of any higher standard of qualification than is absolutely necessary for the protection of the public."

The Office Site Committee reported that the lease of the ground for the Board's new office had been signed, the site cleared, an architect appointed, and the building placed in the hands of a firm of builders.

The Board considered the steps to be taken to provide lectures and instruction, on the lines of post-graduate study, for those who have obtained, or are desirous of obtaining, registration without the possession of a recognized qualification; and the Examination Committee was asked to consider the matter and report.

Dental Registration.

the procedure according to the various categories had been approximately as follows:

For the 6 in practice for five years ...	3,695
Members of Incorporated Dental Society ...	1,700
Pharmaceutical chemists, etc. ...	367
Dental mechanics ...	355
Those in practice for less than five years ...	119
Companies ...	20
Directors ...	23

The demand for copies of the Regulations had been large, and more than 1,500 were sold, realizing upwards of £195.

In response to a suggestion by the British Dental Association the Board resolved that the names of all applicants for registration under Clause 3 of the Dentists Act be published before a certificate is issued.

The appointment of an Assistant Registrar was approved, and the audited accounts of the Dental Fund for the year 1921 were passed.

Correspondence.

Free Choice of Doctor.

SIR.—One of our cardinal points at the time of the Insurance Act fight was free choice of doctor. This seems an opportune moment to suggest that the profession should ask that the insured person should be at liberty to change his doctor at any time; the machinery is already in existence—he would merely have to hand his card to any doctor who was willing to accept him, irrespective of the fact that he might be on the list of a neighbouring practitioner. To meet the case of a patient who was already ill it might be arranged that a transfer of a given number of units—say the value of eight quarterly capitation fees—should be made from the list of one doctor to that of the other. It would be only fair to allow an appeal by either doctor in the event of any individual case proving markedly unfair; probably, in the vast majority of cases, the fixed sum would be accepted without demur, but if it were not the case might be settled by the Panel Committee, unless, of course, the two doctors were able to agree to a modified fee. This arrangement would automatically remove 90 per cent. of all complaints of inattention on the part of the patient and put panel patients in exactly the same position as private patients, avoiding much of the irritation caused at present by the proceedings of Medical Service Subcommittees.—I am, etc.,

West Drayton, Feb. 23rd.

PERCY K. MUSPRATT.

Functions of the School Medical Service.

SIR.—Before the British Medical Association commits itself by advocating the transfer of the School Medical Service from the control of the education authorities to that of the public health authorities it would be as well to consider the arguments that are likely to be directed against this policy.

As against the demand for the integration of all the "health services" there is the equally logical plea for the multiplication of organizations dealing with the welfare of children. Any economies effected by the first policy in preventing medical overlap, etc., will be farcical if this involves the provision of a substitute for the present education organization (upon which, in present circumstances, devolves so many administrative and supervisory duties in connexion with the School Medical Service). This great and growing machinery has such possibilities as a hygienic agency that its artificial separation from all medical functions seems hard to justify.

Apart from general and administrative questions, however, it is at least arguable that medicine has a great and useful

function within the sphere of education proper—that is, as an auxiliary (and hence subordinate) to culture. The promotion of social and mental health—efficiency, stability, and happiness—is a medico-psychological task, but one utterly outside the present scope of the public health services. On the other hand, it is a professed objective of education, with which it has natural affinities and in separation from which it cannot hope to be pursued. Whatever proportion of the present functions and personnel of the School Medical Service should ultimately be transferred to the control of the Health Ministry, a residue which might be called medico-educational must retain its present status.—I am, etc.,

Glasgow, W., Feb. 23rd. IAN D. SUTTIE, M.B., F.R.F.P.S.G.

Cost of Crêpe Bandages.

SIR.—Recently my patients have been complaining of the price charged by chemists for crêpe bandages.

To-day I was informed that the retail cash price for a cotton crêpe bandage 3 in. wide by 6 yards long is 3s., the amount of material in the bandage being exactly half a square yard. Perhaps some of your readers in the districts where this material is worn could find out what is the real cost of production. Surely someone must be making enormous profits.—I am, etc.,

Aldershot, March 2nd.

J. H. GIBSON.

INSURANCE.

LOCAL MEDICAL AND PANEL COMMITTEES.

LONDON.

Limitation of Lists.—Some discussion has arisen between the London Insurance Committee and the Panel Committee on the number of persons for whose treatment a practitioner may accept responsibility under the allocation scheme. It is pointed out by the Insurance Committee that under Clause 6 (vi) of the scheme, which indicates the procedure to be followed in determining whether the numbers on the practitioners' lists conform to the limits fixed by the previous provisions of the clause, it is possible in exceptional cases for a practitioner to have more than 3,000 insured persons on his list. This occurs when the value of the capitation fee falls below the standard value, as it did in London during the last quarter of 1921. The Insurance Committee proposes to press for an amendment of the allocation scheme so that it shall not be at variance with the Medical Benefit Regulations. The Panel Committee, on the other hand, takes a different view as to the effect of the subclause, and at its last meeting passed a resolution affirming the substantial fairness of the clause as a means of computing the number of insured persons on a practitioner's list.

Dispensing of Prescriptions.—The Panel Committee has decided to call the attention of the Ministry of Health to the failure of many chemists in London to display a notice outside their place of business when it is not open stating at what other places in the neighbourhood it is possible to obtain drugs and appliances and at what hours. Many cases have also been reported to the Committee of difficulty in getting prescriptions dispensed near to the closing hour, and the Committee passed a resolution to the effect that it was desirable that a chemist should not refuse to dispense on the same day any prescription presented to him within the hours during which his shop was open.

Medical Records.—The Committee passed a resolution expressing the view that in cases where forms of medical records are returned by reason of the insured persons not records should be preserved, and if wished the original record should be forwarded to the practitioner on whose list the person's name is included, so that he may have the advantage of the records of previous illnesses. It was stated that it is the custom in such cases for a fresh form of medical record to be issued to the practitioner.

Practitioners.—The Chairman of the Committee of the London Insurance Committee reported recently to have expressed the opinion at a public meeting that the process by which a doctor became an insurance practitioner was too easy, and that he would appoint in each area to consider applications for admission to the medical list. A resolution was proposed to direct the Ministry of Health to the address in question, on the ground that the remarks were not consistent with the impartiality which the chairman of a Medical Services Subcommittee should preserve. After some discussion, however, the resolution was lost.

COVENTRY.

At a meeting of the Coventry Panel and Local Medical Committee on March 1st, the Chairman (Dr. W. H. Lowman) presiding, a thorough consideration was given to the contents of the recent circular issued by the National Insurance Defence Trust, and it was resolved to ask each insurance practitioner in the area for authority for the current voluntary levy to be increased to a penny capitation fee in all, in order to enable the Panel Committee to make an annual contribution of the proceeds of a halfpenny capitation levy towards the purposes of the Trust, this action to be subject to the consent of two-thirds of the local practitioners.

A resolution was unanimously adopted strongly urging that the provision for insured persons of nursing, hospital, dental, and

lithalmic treatment is undoubtedly of the nature of medical benefits within the spirit of Section 14 of the 1911 Insurance Act, asking accordingly that arrangements for the administration of such additional benefits should be made in the locality by and through the Insurance Committee, as opposed to the present undesirable and chaotic arrangements.

A query having been received from a local insurance practitioner to whether autogenous vaccines could be ordered if desired, led a thorough examination of the position. It was unanimously agreed to reply that an autogenous vaccine might be ordered for insured patient if his medical attendant considered this necessary for adequate treatment and was prepared to justify his action to the Panel Committee. It was also agreed that in the case of thorough such vaccines should be obtained through the agency of panel chemist and paid for in the normal course of the monthly chemists' settlement.

Naval and Military Appointments.

ROYAL NAVAL MEDICAL SERVICE.

The following appointments are announced by the Admiralty: Surgeon Lieutenant Commander E. S. Mellor to the *Merlin*, Surgeon Lieutenant E. Clark to the *Campbell*. To be Lieutenants: D. F. McGregor and D. B. Joyce, and appointed to Haslar Hospital for course.

ROYAL ARMY MEDICAL CORPS.

Lieutenant-Colonel J. C. Kennedy to be temporary Colonel whilst specially employed, January 3rd, 1922 (substituted for notification in the *London Gazette*, February 8th, 1922).

Lieutenant-Colonel and Brevet Colonel R. S. Hannay, C.M.G., D.S.O., to be temporary Colonel, vice Lieutenant-Colonel and Brevet Colonel H. G. Martin, M.C.

The following officers are restored to the establishment: Major H. S. Jackson, from the half-pay list, with precedence next below Major G. F. Wilson, M.C., Captain G. D. R. Carr, M.C.

Captain C. L. Balkwill retires, receiving a gratuity. Temporary Captain J. H. Porter, M.C., relinquishes the acting rank of Major, October 1st, 1918 (substituted for notification in the *London Gazette*, March 2nd, 1919).

Temporary Captains relinquish their commissions and retain the rank of Captain: O. T. J. C. de H. Clayre, R. Stephens, Lieutenant (temporary Captain) F. K. Escribitt to be Captain.

ROYAL AIR FORCE MEDICAL SERVICE.

Lieutenant C. Ransford is granted a temporary commission as a Flight Lieutenant with effect from and with seniority of February 15th, 1922.

TERRITORIAL ARMY RESERVE.

ROYAL ARMY MEDICAL CORPS.

Major E. Gray, having attained the age limit, is retired and retains the rank of Major with permission to wear the prescribed uniform. Captains R. W. Simpson, W. Bain, I. D. Stubbs, and D. P. H. Gardiner relinquish their commissions and retain the rank of Captain.

The following officers, having attained the age limit, are retired and retain their ranks: Major D. E. Dickson (with permission to wear the prescribed uniform), Captains J. B. Smith, A. L. McCully, J. Aitken.

DIARY OF SOCIETIES AND LECTURES.

Medical Society of London, 11, Chandos Street, W.1.—Mon., 8.30 p.m., Discussion on the Differential Diagnosis of the Common Exanthemata, to be opened by Dr. E. W. Goodall, and followed by Sir John Broadbent, Dr. J. Rolleston, Dr. F. Foord Caiger, Dr. Frederic Thomson, Dr. A. Cameron, and others.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.—Tues. and Thurs., 5 p.m., Milroy Lectures by Dr. Major Greenwood: The Influence of Industrial Employment on General Health.

ROYAL SOCIETY OF MEDICINE.—Section of War: Mon., 5.30 p.m., Pharmacological. Tues., 4.30 p.m., J. Anrep: Experimentation on Conditional

Reflexes. Section of Psychiatry: Tues., 8.30 p.m., Adjourned Discussion: The Ideal Clinic for Nervous and Borderland Cases. Section of History of Medicine: Wed., 5 p.m., Dr. Herbert R. Spencer: Obstetrical Works of Scipione Mercurio. Paper.—Mr. F. Homer: A Short History of Bonsettling. Section of Dermatology: Thurs., 4.30 p.m., Cases: Dr. J. Darier (Paris): Des cancers épithéliaux de la peau. Dr. Darier will be entertained to luncheon at the Trocadero Restaurant at 1 p.m. Tickets 7s. 6d. exclusive of tax. Attendees should notify Dr. Barber, Secretary, at 10, Bedford Square, W.1. Section of Otolaryngology: Fri., 4.45 p.m., Therapeutics: Fri., 8.30 p.m., Discussion on Subjects Rendered Unconscious in the Theatre, to be opened by Dr. Morrison and Mr. Levy and Prof. MacWilliam.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, Royal Army Medical College, Millbank, S.W.—Laboratory meeting, Thurs., 8.15 p.m., Demonstrations by Lieutenant-Colonel H. M. Perry, Lieutenant-Colonel W. P. MacArthur, Major J. A. Manifold, Major S. Elliott, Lieutenant-Colonel Clayton Lane, Major H. C. Brown, and Dr. H. M. Woodcock.

POST-GRADUATE COURSES AND LECTURES.

ROYAL HOSPITAL, Fulham Road, S.W.—Tues., 4 p.m., Dr. Leitche: Experimental Production of Cancer. Fri., 4 p.m., Mr. P. P. Cole: The

BRITISH MEDICAL ASSOCIATION, Chesterfield 30 to 4 p.m., Dr. Yates: Neurasthenia; Dr. Wilkinson: Symptoms of Danger in Ear Cases.

INBURGH ROYAL HOSPITAL FOR SICK CHILDREN.—Thurs., 5 p.m., Mr. J. Fraser: Modern Methods of Treatment of Bone and Joint Tuberculosis.

ASGOW POST-GRADUATE MEDICAL ASSOCIATION, Royal Maternity and Women's Hospital.—Wed., 4.15 p.m., Dr. J. H. Martin: Obstetrical Cases.

HOSPITAL FOR SICK CHILDREN, Great Ormond Street, W.C.1.—Thurs., 4 p.m., Mr. H. T. Gray: Intestinal Obstruction.

CHESTER BABINS' HOSPITAL, Slade Lane, Levenshulme.—Sat., 4 p.m., Dr. Chisholm: Malnutrition.

MANCHESTER: ANCOATS HOSPITAL.—Thurs., 4.30 p.m., Dr. Stirling: Iritis lacrima.

MANCHESTER ROYAL INFIRMARY.—Tues., 4.30 p.m., Dr. T. H. Oliver: Diabetes.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westminster Street, W.1.—Daily, In- and Out-patient Attendances, Mon., 5.30 p.m., Lecture by Dr. Price: The Heart in Relation to Life Assurance.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen Square, W.C.1.—Mon., Tues., Thurs., and Fri., 2 p.m., Out-patient Clinics. Tues. and Fri., 9 a.m., Surgical Operations. Lectures.—Mon., 12 noon, Dr. Greenfield: Neurophysiology. Tues. and Fri., 3.30 p.m., Dr. Saunders: Cranial Nerve Lesions. Thurs., 3.30 p.m., Dr. Howell: Hy-taria.

NORTH OF ENGLAND BRANCH, BRITISH MEDICAL ASSOCIATION, Durham County Hospital.—Fri., 2.15 p.m., Scientific Demonstrations.

ROYAL INSTITUTE OF PUBLIC HEALTH, 4 p.m., Dr. W. H. Dickinson: Isot Dispensary Work.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Onseley Road, Balham.—Thurs., 4 p.m., Mr. Zachary Cope: A Demonstration Lecture on Common Sprains and Their Treatment.

ST. MARTIN'S HOSPITAL, GENERAL DISPENSARY, 77, Welbeck Street, W.1.—Dr. E. P. Steward: Infant Welfare Course, 6 p.m., Wed., The Feeding of Children between 9 Months and 2 Years; Fri., Dietetic Treatment of Young Children in Certain Common Complaints.

WEST LONDON POST-GRADUATE COLLEGE, Hammersmith, W.—Daily, 10 a.m., Ward Visits; 2 p.m., In- and Out-patient Clinics and Operations. Lectures.—5 p.m., Mon., Dr. S. Pinehio: Fibrosis of Lung. Tues., Dr. G. Pernet: Affections of the Scalp, Syphilis and otherwise. Wed., Mr. MacDonald: Retention of Urine. Thurs., Sir Clifford Allbutt: Angina Pectoris Lecture open to all medical practitioners. Fri., Mr. Simmonds: Osteomyelitis and Its After-effects.

British Medical Association.

OFFICES AND LIBRARY, 429, STRAND, LONDON, W.C.2.

Reference and Lending Library.

THE READING ROOM, in which books of reference, periodicals, and standard works can be consulted, is open to members from 10 a.m. to 6.30 p.m., Saturdays 10 to 2.

LENDING LIBRARY: Members are entitled to borrow books, including current medical works; they will be forwarded, if desired, on application to the Librarian, accompanied by 1s. for each volume for postage and packing.

Departments.

SUBSCRIPTIONS AND ADVERTISEMENTS (Financial Secretary and Business Manager). Telegrams: Articulate, Westrand, London).

MEDICAL SECRETARY (Telegrams: Mediseera, Westrand, London). Editor, *British Medical Journal* (Telegrams: Aitology, Westrand, London).

APPOINTMENTS.

HIGHAM, J. Parkinson, M.B., B.S. Durh., Consulting Ophthalmic Surgeon to the Holgate and Broomlands Hospitals, Middlesbrough.
MANCHESTER ROYAL INFIRMARY.—Assistant Medical Officer (Central Branch): Miss Isobel M. M. Aitken, M.B., Ch.B., D.P.H. Assistant Surgical Officers (Central Branch): W. H. Douglas, M.C., M.B., Ch.B., F.R.C.S.; E. E. Hughes, M.B., Ch.M., F.R.C.S. Junior House-Surgeon (Specials Department): J. W. Smith, M.B., Ch.B.

BIRTHS, MARRIAGES, AND DEATHS.

The charge for inserting announcements of Births, Marriages, and Deaths is 9s., which sum should be forwarded with the notice not later than the first post on Tuesday morning, in order to ensure insertion in the current issue.

MARRIAGE.

GRIFFITH-WILLIAMS-GILLET.—On February 28th, at St. Andrew's Church, Eaton, by the Rev. H. S. Clarke, Rector, Arthur Griffith-Williams, M.R.C.S., L.R.C.P., of Mattishall, Norfolk, only son of the late William Henry Griffith-Williams, L.R.C.S., L.R.C.P., and grandson of the late George Griffith-Williams, Vicar of Penbryn, Cardiganshire, to Dorothy Isobel Gillett, of the Old Hall, Colton, Norfolk, second daughter of the late Robert Howard Gillett, of Halvergate.

British Medical Journal.

SATURDAY, MARCH 11TH, 1922.

THE MEANING OF DEATH RATES.

It is to utter the merest commonplace to say that the technical developments of medicine, and of the arts and sciences ancillary to medicine, have become so extensive that there is a real need of monographs which, although of "popular" in the too frequent sense of that word—the sense which implies that the author is talking down to the reader—do focus attention upon principles. A monograph by Dr. John Brownlee on the use of death rates as a measure of hygienic conditions, just published by the Medical Research Council,¹ discusses the principles of a method of investigation which is far from being the least technical and specialized of our instruments of inquiry. Although we all use death rates to point morals and adorn tales, we have not all clear ideas as to the advantages and disadvantages of different ways of measuring a death rate. In the ordinary medical curriculum there is no instruction in medical statistics—even in the course for diplomas in public health there is very little; the recent proposals of the General Medical Council do not afford any assurance that a serious training in vital and medical statistics will become a normal part of the course of English post-graduate training. Most medical men, we fancy, know that there are three ways in which the facts, or some of the facts, of mortality can be expressed—namely, by relating the deaths to population without regard to age, the "crude" death rate; by expressing the death rates at ages in terms of particular population, the "standardized" death rate; and by constructing a "life table." Most medical men now that the first method is liable to be misinterpreted, believe that the second is more useful, and imagine that the third is intelligible only to mathematicians, but, when understood, far more valuable than the others. Dr. Brownlee set himself the task of explaining the merits and shortcomings of the various measures, and has produced a report which is not only valuable but interesting. Of course Dr. Brownlee does not confine himself to this comparison; his monograph contains original contributions both to epidemiology and to the technique of vital statistics, but we shall here only discuss his remarks on the general theme.

Briefly, Dr. Brownlee's conclusion is this: hygienic inferences ought only to be drawn from a comparison of standardized death rates if the latter are connected with life-table death rates in such a way that standardized death rates can be converted easily into life-table death rates. Thus the standardized death rate from all causes together is so related to the life-table death rate, as also are the death rates from pneumonia and from Dr. Brownlee's types of phthisis. Hence it does not in these cases matter which method is employed. But for such diseases as cancer or nephritis there is no simple relation between standardized and life-table scales, and in these cases hygienic inferences ought not to be drawn from standardized mortality rates. Although the standardized death rates from cancer are higher in urban than in rural districts, the life-table method shows that, "taking an equal number of persons living above the age of 15 years, exactly the same proportion is destined to die from cancer whether the individuals live in a rural district, an urban district, or in a county borough."

Dr. Brownlee, it will be seen, has an even higher opinion of the life-table method than Dr. Farr had; his judgement of the value of any other method depends upon the degree to which the other method reproduces the teaching of a life table. On the other hand, we recently read, in a journal devoted to actuarial science, a criticism of the Registrar-General's abridged life tables which contained something very like a sneer at the supposed enthusiasm of medical officers of health for the calculation of life tables. It may therefore be of interest to inquire whether any of the arguments against the primacy of the life table—all, we think, mentioned by Dr. Brownlee with the candour which distinguishes his papers—deserve to be emphasized. The first and most important is that a district life table is as much a statistical fiction as is a standardized death rate. Were there any rural district or county borough entrance to which was restricted to those born within its boundaries and from which nobody could escape except by death, the life table of that district would be a perfect translation of the facts of mortality. The meaning of the translation from the hygienic point of view might still not be easy to make out, unless the sanitary conditions of the district were unchanged throughout a generation, yet the statistical translation would be perfect. But in England and Wales there are no such closed areas, and the actual life tables are only statistical fictions. They tell us how a hypothetical population would die out if through a whole generation those rates of mortality were to prevail which prevailed amongst members of different generations observed contemporaneously over a small number of years—at most ten years. Since there is a great deal of internal migration, and since the death rates at ages are not constant from decennium to decennium, it is evident that a district life table does not approximate at all closely to the *Absterbeordnung*, the Order of Dying, of a real human generation. Therefore, if this method gives an answer to some question different from that given by, say, the method of a standardized death rate, it does not follow as an irresistible consequence that one answer is right and the other wrong.

To apply these reflections to the particular case chosen by Dr. Brownlee—that of cancer—his point is that the reason why the standardized death rate of the urban districts is greater than that of the rural districts is that people of the same age in years in town and country are not of the same physiological age; "the necessary allowance," he says, "for the ageing of the body experienced in towns over that experienced in the country must thus first be made before any differentiation between the amounts of cancer present in different districts is justifiable, though here the possibility of local ageing of tissues must not be overlooked, a phenomenon well known when problems of local immunity are the seat of question." But if, as Dr. Brownlee says, "cancer is commonly believed to be a degenerative disease," and if this belief be true, we are left in some doubt as to what remains to be justifiably compared after the desired allowance has been made. It might be urged that this ageing of the tissues is precisely what we wish to study, that we wish to know *why* the tissues are more senescent at a given age in one district or type of community than in another. If in a series of districts the numbers of life-table decedents from cancer at ages over 15 are equal, does it really follow that the average etiological factors of cancer are identical qualitatively and quantitatively in all?

This objection is, we think, much the most formidable in the way of accepting life-table death rates as ultimate criteria of mortality for the purposes of the sanitarian, and we are not sure that Dr. Brownlee's arguments have removed it. The more usual objection, that life-table constants are difficult to compute, is of little moment.

¹ Special Report No. 60, Medical Research Council, published by H.M. Stationery Office, London, 1922, pp. 53, price 1s. net.

The method of Dr. Snow, used in the Registrar-General's recent collection of district life tables, and Dr. Brownlee's own method, described in the paper under notice, are easy to understand and handy in application. Dr. Brownlee's critique may justifiably excite distrust of inter-local comparisons of rates of mortality, whatever standard of comparison be adopted, whether that of life tables or another.

Dr. Hamer has often called attention to the way in which migration, both internal and external, complicates the problem of geographical comparisons. This difficulty cannot be overcome by any manipulation of the data we now have. Perhaps the intensive study of small samples—a method which in the hands of Professor Bowley has yielded valuable economic results here and has been applied in America to the study of hygienic problems—will prove to be the solution. We do not mean to say that all has now been learned from general routine statistics of mortality which can be learned. Farr showed how much more than a simple arithmetical profit and loss account could be made up from the mortuary registers. Since his time other statisticians, amongst whom Dr. Brownlee himself holds an honourable place, have come nearer still to the centre of the labyrinth, and no man can say that further progress is impossible. But something akin to the collective investigations which the British Medical Association promoted some forty years ago seems to be a need of the time. We are now in a much better position to carry out such investigations than we were even a generation ago. On the purely statistical side knowledge of the conditions and limitations of sampling and of the methods by which the significance of averages based upon samples may be appraised is more diffused, and the training of field workers is easier. Such a study as Dr. Perry's, of the American Cotton Industry,² suggests lines of inquiry which could be followed in England with greater ease than in the United States, and, although involving peculiar difficulties, would at least not be subject to those ambiguities which inhere in the massed records of our official departments. While we do not agree with all the conclusions reached by Dr. Brownlee, it is a pleasure to express our appreciation of the value of his monograph. Dr. Brownlee deserves what we think he would regard as the highest praise—namely, a comparison between himself and Farr. He has not, we think, equal powers of literary expression, and hardly carries his learning as easily as his spiritual ancestor. But he has the same large philosophical grasp, the same perception that the statistical method is a means to an end, that end being the revelation of the biological factors of life and death, of disease and health. The medical officer of health who reads his papers will learn a good deal about statistical methods; he will also learn what is even more important—something of the goal to which all medical statisticians and biometricians are striving.

THE X-RAY TREATMENT OF UTERINE FIBROIDS.

NONE of the applications of x-ray therapy are more important or fraught with greater interest than that to the treatment of fibromyomata of the uterus. While it is true that the method has acquired greater popularity in America and on the Continent, yet that British gynaecologists are, on the whole, keenly alive to its possibilities and advantages was abundantly demonstrated by the joint discussion between the Sections of Obstetrics and Gynaecology, and Electro-Therapeutics, at the British Medical Association Meeting at Cambridge

in July, 1920.¹ Put briefly, the participants in the discussion were agreed upon certain well-defined contraindications to the treatment, and in the assumption that there is a distinct place for the use of x rays in the treatment of selected cases of uterine fibroids. They were agreed that it is unsuitable for women under 40 because of the premature and unusually severe vasomotor phenomena found to ensue; for submucous fibroids and very large fibroids of any variety; for cases in which the tumour is undergoing degeneration or complicated by pelvic inflammatory conditions, old or recent, by the presence of malignant disease, of an ovarian cyst, or of pregnancy; and according to Dr. Herbert Williamson, when the patient is gravely anæmic with a red blood cell count of less than 2½ million, and the haemoglobin less than 35 per cent.

In a recent article² Bécclère submits the results of 300 new observations on patients whom he had not only examined but irradiated himself, and whose after-history he had carefully followed. A perusal of his article reveals radical differences between his practice and that of his more conservative British colleagues. Thus, of the 300 cases, 49 were below the age of 40. "Time was," he says, "when Roentgen therapy was only admitted in women above 40. It has, however, been abundantly proved that not only below 40 but even below 30 years it is followed by the same success as at a more advanced age. The youth of the patient has ceased to be a contraindication." He has not observed any appreciable difference between the natural menopause and that induced by x rays. Indeed, most of the patients afterwards enjoyed better health than for many years, owing, no doubt, to the arrest of hæmorrhage. On the point of the abnormal severity of the artificial menopause Williamson is, however, very emphatic, and states that he has on several occasions seen distressing and prolonged vasomotor phenomena follow the treatment in women under 40, producing symptoms which were not relieved by extracts of the endocrine glands; in three cases he has seen kraurosis vulvæ develop with severe dyspareunia. Such symptoms can, of course, be avoided by hysterectomy with conservation of the ovaries. On the other hand, the views expressed at Cambridge by Dr. Louisa Martindale were in agreement with those of Bécclère. She said that "the menopause produced was freer from symptoms than the normal climacteric." And again, x-ray treatment "brings about a climacteric involving less disturbance even than a natural one."

According to Bécclère, the decision for or against the use of x rays is not to be determined by the size of the tumour; in 159 of his cases it was such dimensions as to extend to a height varying from 10 to 34 cm. (4 to 13 in.) above the symphysis pubis; compression of neighbouring organs, even the bladder, so far from being regarded as a contraindication is looked upon as an indication for the employment of x rays. "Size," he says, "is never a contraindication to the use of x rays." In many of the cases the tumours reached above the level of the umbilicus, while some even extended underneath the costal margin. He recognizes, however, that in the case of such large tumours diminution in size can only be expected to reach a point at which it becomes just bearable to the patient, and that in such cases surgical interference gives a more complete result. The patient should be informed of the relative advantages of the methods, and allowed to choose. But if operation is contraindicated or is refused, "the largest myomas may be treated with success by Roentgen therapy." This is Bécclère's position on this point and does not differ materially from that of his British colleagues.

The "aseptic degenerations"—myxomatous, calcareous and necrobiotic—Bécclère does not look upon as contra-

² Bulletin No. 251 of the United States Bureau of Labour, Washington, 1919.

² Bull. de l'Acad. de Méd., T. lxxxvi, p. 151.

indications. Of conditions in the tumour itself, "only septic complications, torsion of the pedicle, or grave hæmorrhage necessitate surgical intervention, whilst all the other conditions, formerly looked upon as contra-indications, can no longer be considered as such."

In Bèclère's experience the only risk attending the treatment was the possibility of producing a form of dermatitis which might be followed by trophic disturbance of the skin of the abdomen. It is a danger easily avoided by using a proper method and precise dosage. In none of his 300 cases did he observe the least cutaneous accident, except that frequent temporary brown pigmentation which he looks upon as a normal phenomenon. Sometimes on the same day or the day after the treatment the patient suffered from a condition resembling sea-sickness—the "Roentgenkater" of the German radiologists, called by the French "mal des rayons." Only exceptionally did it end in vomiting, and in no case did it necessitate the patient remaining in bed.

In view of results so excellent, obtained by a technique admittedly in many important respects imperfect, it seems strange that radiotherapy has not been more widely and generally adopted in this country for the treatment of uterine fibroids, more especially as it seems probable that, with increased experience, the results would rapidly improve. We know of famous British schools of medicine in which the only resort in the treatment of fibroids is still surgical operation.

THE ROBERT CAMPBELL MEMORIAL ORATION.

THE first Robert Campbell Memorial Oration was delivered on February 16th, at the Medical Institute, Belfast, by Mr. Thomas Sinclair, C.B., F.R.C.S., Professor of Surgery in the Queen's University, and Surgeon to the Royal Victoria Hospital, Belfast. Sir John Walton Browne, M.D., was in the chair, and there was a very large attendance of the profession; a few of the late Mr. Campbell's relations and intimate friends were also present. Mr. Sinclair began by recalling how, after Robert Campbell's death at the early age of 55, his friends and colleagues resolved that the tribute they desired to pay would better find expression in the establishment of a biennial memorial lecture, by which the advance of surgery and research might be promoted, rather than by seeking to enshrine his well-known personality in some form of pictorial or plastic art. Mr. Sinclair then sketched the outstanding incidents of Campbell's life. He was the second son of the Rev. Robert Campbell of Templepatrick, and a brother of the distinguished gynaecological surgeon Dr. John Campbell of the Samaritan Hospital, Belfast. After a brilliant academic career in Arts and Medicine, during which he seemed the highest honours at every step, he graduated in the Royal University of Ireland as first man of his year. Later on he added the Fellowship of the Royal College of Surgeons of England, after further study in Trinity College, Dublin, and St. Thomas's Hospital, London. He was for a time house-surgeon to the Chester Infirmary, but shortly was appointed surgeon to the Children's Hospital in Belfast and to the Royal Victoria Hospital. From time to time he published papers on operation for perforated typhoid ulcer, exophthalmic goitre, and fractures of the head of the radius, and was one of the first to recognize the importance of acid intoxications as a cause of death after chloroform anaesthesia; but his most notable achievement was his pioneer work in the radical cure of hernia in infants and young children. At a time when radical cure was reserved for older children, say from 5 to 9 years of age, Campbell demonstrated that no child was too young to be treated in this manner, and that such cases might in many instances be treated as extern patients after operation. His first paper concerning twenty cases was read before the annual meeting of the British Medical Association at Portsmouth, and the popularizing of the early adoption of this practice may be said to date from this period. Stiles

of Edinburgh followed the next year with an account of 100 cases, but assigned the age of 2 years as a limit. Campbell in later years extended his series to 1,500 cases with only one death, and that from delayed chloroform poisoning, and with only three cases of sepsis in the wound. Campbell was the first to show that at the start cases of appendicitis fell into two categories, one primarily obstructive leading to gangrene and perforation with paroxysmal pains like strangulated hernia, little or no tenderness, rigidity or fever, these symptoms being followed in a day or two when inflammation supervened. Such a train of symptoms brooked no delay in operation. In contrast with these were cases of appendicitis inflammatory from the onset, with fever, tenderness, rigidity, elevation of pulse, and a more continuous, if less violent, type of pain. Such attacks might recur again and again over months or years; the anxieties were not so acute as in the former type, and temporizing in these primarily inflammatory cases was not so disastrous, though prompt operation was safest in both types. In conclusion Mr. Sinclair touched lightly on Robert Campbell's personal qualities, his social graces, his kindness of disposition, his high standard of honour, and his generosity. He furnished an admirable example to the rising generation of surgeons, who should keep before them his engaging personality, which was the embodiment of the best traditions of our profession. It was a pleasure to hear this testimony in the presence of Mrs. Campbell, who had been a powerful factor in her husband's successful career. Mr. Sinclair then proceeded to make the remarks on the surgery of the blood which are reported at page 375. At the conclusion of the oration a vote of thanks to Mr. Sinclair was cordially adopted, on the motion of Professor J. A. Lindsay, Professor of Medicine in Queen's University, seconded by Dr. John Morrow, physician to the Royal Victoria Hospital.

NATIONAL COLLECTION OF TYPE CULTURES.

THE Medical Research Council has issued a catalogue* of the national collection of type cultures, to the formation of which at the Lister Institute we have on several occasions made reference. The need of such a collection has long been felt in many directions, and particularly in medical research work, both for the study of principles and methods in bacteriological investigations and for the systematic classification of the various species and strains of bacteria and protozoa. Before the war M. Binot's collection at the Pasteur Institute in Paris was very helpful to workers here, as was a collection of type cultures, first formed on a commercial basis by Kril at Prague, and subsequently maintained by the Serophysiological Institute in Vienna. The Museum of Natural History in New York has for some years maintained a culture bureau, which has helped workers here, not only by the provision of authentic cultures, but also by the studies in classification made by its staff. In this country the Lister Institute of Preventive Medicine has for many years assisted bacteriologists, both at home and abroad, so far as the resources of its own private collection permitted, and two years ago the Medical Research Council was able to make arrangements for the maintenance there of a national collection of type cultures, the governing body of the Institute undertaking to provide all necessary facilities. The collection is under the direction of Dr. J. C. G. Ledingham, F.R.S., a member of the staff of the Institute, assisted by a curator, Dr. R. St. John Brooks, and an assistant curator, Miss M. Rhodes, appointed by the Medical Research Council. Attention has been concentrated primarily upon obtaining fully authenticated strains of pathogenic organisms, but bacterial and protozoal strains of economic importance are being added as opportunity offers. The staff of the collection, which is also experimenting with economical and labour-saving methods of sub-culture, is prepared to help in the identification of strains received from workers at home or abroad. It is hoped that such workers will reciprocate by presenting new material to the collection

* London: H.M. Stationery Office or through any bookseller. (Price 1s. 6d. net.)

for permanent maintenance. In the present position of the problems involved in the classification of micro-organisms, the names in the main catalogue have been arranged in alphabetical order, and a subject index has been added giving cross-references under etiological headings. In the nomenclature employed long-established usage has been followed, but the need for international uniformity is recognized, and it is hoped in future editions to take fuller cognizance of the labours of systematists in this and other countries. The scope of the collection has been extended to include fungi of importance in plant-pathology, medicine, veterinary science, technology, and soil biology. This part of the collection will be managed by a committee appointed by the British Mycological Society, and of which the curator of the National Collection is a member. The annual lists of the mycological collection will be published in the *Transactions* of the society. The Council invites the co-operation of bacteriologists, and it asks that cultures sent either for identification or for maintenance in the collection should be accompanied by full particulars as to source and date of isolation, and if possible by clinical and epidemiological notes. All communications should be addressed to the Curator, National Collection of Type Cultures, Lister Institute, Chelsea Gardens, London, S.W.1.

PROPHYLAXIS AGAINST TYPHUS FOR TRAVELLERS.

A practitioner is nowadays asked with increasing frequency by patients who have to travel in Poland or the Near East as to what precautions can be taken against typhus fever. The advice is not easy to give. Unlike typhoid fever, no effective method of immunization against typhus is known. Various protective and therapeutic serums have been described by foreign observers, such as that of Drs. Nicolle and Blagot,¹ and, more recently, interesting and promising experiments in immunizing monkeys with living virus have been described by Professor Kusama, of Tokio,² but prophylactic vaccine therapy against typhus remains entirely in the experimental stage. Even were it possible to procure it in this country, there is no serum or vaccine which can be recommended in any sense as of proved value. Nor is this surprising when we consider the uncertainty which still surrounds the causal organism. Apart, therefore, from the ordinary rules of hygiene, such as the avoidance where possible of over-fatigue, filth, overcrowding, and areas known to be heavily infected, the traveller must for the present rely on those precautionary measures which consist entirely in the avoidance and destruction of lice. It will probably not be necessary for the ordinary English traveller to take all the precautions recommended to doctors or nurses who are actually in attendance upon typhus patients, such for example as the special "louse proof" combined linen under-garments or the top boots which are thought to defy louse invasion from the floor. Frequent changes of underclothing are, however, desirable, and if the places visited are infected with typhus or known to be heavily infested with lice, a rigorous search should be made at least twice a day for the parasites; if frequently and thoroughly done, merely searching, picking, and brushing the underclothes can accomplish a good deal. Frequent change of underclothing is advantageous even in the absence of facilities for washing the clothing removed. Cold and fasting are abhorrent to the louse. The hair should be kept short and baths taken when possible. For the ordinary traveller probably the most convenient way of "delousing" infested underclothing is to soak it in a solution of lysol for twenty minutes in a strength of 2 per cent. if cold, or 1 per cent. if hot water be available. Baking, boiling or soaking in petrol are also efficacious. A hot flat-iron applied along the seams is a simple and effective method, if available. Anti-louse applications for the clothing are innumerable. Powdered naphthalene (or ointments containing naphthalene) is probably the best and least objectionable to the user. The ordinary pyrethrum insect powder avails little against the louse.
